Abstract

Autoimmune damage to the kidneys which can be triggered by various autoantibodies may cause a range of nephropathies. These autoantibodies may target specific renal structures like the glomerular basement membrane, resulting in primary diseases like anti-GBM disease, or they may be part of a systemic immune process such as vasculitis or systemic lupus erythematosus. There are also some other less common but serious systemic autoimmune conditions like antiphospholipid syndrome, which mainly causes thromboses via autoantibodies, may affect the kidneys, and causes devastating complications.

The evolving medical literature gives us more insight into even rarer autoimmune conditions affecting the renal system like cryoglobulinemic vasculitis or immunoglobulin G4-related disease. Although seen relatively rare in the pediatric population, autoantibody-related kidney damage may cause important morbidity, end-stage renal disease, and mortality. Recognition of these rare but important conditions is of paramount importance to make a correct diagnosis and introduce prompt treatment.

Synonyms

Goodpasture disease or syndrome; Non-anti-neutrophil cytoplasmic antibody (ANCA) associated small vessel vasculitis

Introduction

Autoimmune diseases affecting the kidney are relatively rare but can cause significant morbidity and mortality in the pediatric age. The target of autoantibodies may primarily be the kidney as anti-glomerular basement membrane (anti-GBM) disease and membranous nephropathy or renal damage may occur secondary to non-organ-specific autoantibodies such as systemic lupus erythematosus (SLE) and renal vasculitis.

The clinical presentation of autoimmune diseases with renal involvement is quite heterogeneous depending on the underlying disease.

Table 1 Examples of autoimmune diseases affecting the kidney and associated autoantibodies

Antiphospholipid syndrome	Lupus anticoagulant, anticardiolipin, anti-β2-glycoprotein-I antibodies
Cryoglobulinemia	Type I, II, III cryoglobulins
Immunoglobulin G4-related disease	Immunoglobulin G4
Anti-glomerular basement membrane disease	Anti-glomerular basement membrane antibodies
Systemic lupus erythematosus	Anti-dsDNA, antinucleosome autoantibodies
Renal vasculitis	Antineutrophil cytoplasmic antibodies
Primary membranous nephropathy	Anti-phospholipase A2 receptor antibodies, anti-thrombospondin type-1 domain-containing 7A antibodies
Atypical hemolytic uremic syndrome	Anti-complement factor H autoantibodies

Antiphospholipid syndrome (APS) may come to clinical attention with recurrent thrombosis or gestational problems in adolescent girls, whereas immunoglobulin G4-related disease (IgG4-RD) may present with autoimmune pancreatitis, cholangitis, lymphadenopathy, or orbital diseases. Kidney involvement widely ranged from thrombosis of renal vessels to glomerular diseases with the risk of end-stage renal disease.

Several autoantibodies have been shown to be associated with kidney involvement. A large variety of tests is now available to detect these autoantibodies which make early diagnosis and interventions possible (Table 1).

Antiphospholipid Syndrome

Antiphospholipid syndrome is a systemic autoimmune condition characterized by thrombosis and gestational morbidities associated with persistently positive pathogenic antiphospholipid antibodies (aPLs), including lupus anticoagulant (LA), anticardiolipin antibodies (aCL), and/or anti-β2-glycoprotein-I antibodies (aβ2-GPI) of immunoglobulin (Ig) G and/or IgM isotypes [66].

This condition is rare, and its precise incidence and prevalence in children are unknown. Pediatric APS refers to patients in whom the onset of APS is before 18 years of age. The criteria for diagnosis of pediatric APS are mainly based on adult Sapporo criteria, which are poorly validated in children [2]. The updated criteria used for diagnosis of APS in adult patients require at least one clinical event and one persistently positive aPL test (on two or more occasion at least 12 weeks apart) (Table 2) [66]. For pediatric APS generally, a positive aPL, on two or more occasions at least 12 weeks apart, in the setting of thrombosis is considered diagnostic. Although APS in children presents primarily as vascular thrombosis, less frequently it can present with isolated neurological and/or hematological disease.

APS may have diverse presentations like vascular events, gestational morbidity, catastrophic antiphospholipid syndrome (CAPS), asymptomatic aPLs, and non-classification criteria manifestations like autoimmune cytopenia, skin lesions, valvular heart disease, and APS nephropathy [57, 70]. Since the adult classification may lead to missed or delayed diagnoses in children, the “Single Hub and Access point for pediatric Rheumatology in Europe (SHARE) initiative” has developed recommendations for the diagnosis and treatment of childhood APS [39]. Besides the same laboratory criteria, non-thrombotic manifestations (hematologic, dermatologic, etc.) should be considered for the classification of pediatric patients.

In children 40–50% of APS is primary [5, 104]. Secondary APS constitutes around 50% of pediatric cases, most commonly due to SLE [5]. Primary APS tends to affect younger patients, and arterial thrombosis is more common. Patients with secondary APS, on the other hand, were older and show hematological and dermatological features and venous thrombosis [5].

Since there are overlapping features of SLE and APS, it is difficult to distinguish primary from

Table 2 Classification of antiphospholipid syndrome. (Updated Sapporo criteria. Adapted from Miyakis et al [66])

Clinical criteria	Vascular thrombosis	One or more episodes of arterial, venous, or small vessel thrombosis excluding superficial venous thrombosis
	Gestational morbidity	$\geq$1 unexplained deaths of a morphologically normal fetus $\geq$10 weeks' gestation
		$\geq$1 premature deliveries of a morphologically normal neonate <34 weeks' gestation
		Three or more consecutive spontaneous abortions before 10 weeks' gestation
Laboratory criteria	Two or more occasions, at least 12 weeks apart	Lupus anticoagulant (plasma)
		Medium- to high-titer anticardiolipin IgG and/or IgM antibody (serum or plasma)
		Titers >99th percentile of anti-β2-glycoprotein-I IgG and/or IgM antibody (serum or plasma)

secondary forms of APS. Almost 30% of children with primary APS show SLE or lupus-like disease during follow-up [5]. Patients with SLE might later develop APS. In a study on 57 children with SLE, 14% developed APS over 3-year follow-up [16]. Secondary APS has been seen in patients with juvenile idiopathic arthritis, but with rare thrombosis and less pathogenic aPLs [4]. Other diseases associated with secondary APS are IgA vasculitis, polyarteritis nodosa, Behçet disease, hemolytic uremic syndrome (HUS), and immune thrombocytopenic purpura [5, 67, 103].

Pathogenesis

The pathophysiology of APS is multifactorial and mainly results from the effects of aPLs on procoagulant factors and impaired fibrinolysis. For the development of antibodies, infectious triggers and rheumatological diseases have been proposed.

Antiphospholipid antibodies can be found in healthy children as well, but thrombosis is rare. The mechanism of generation of antibodies is unclear but might be due to molecular mimicry following infections or immunization. Low titers of aCL and aβ2-GPI antibodies were shown in 11.4% and 8.6% of healthy children, respectively [3]. Even infants may produce nonpathogenic anti-β2-GPI antibodies against antigens such as bovine β2-GPI found in milk or beef.

Antibodies in the disease process target not only phospholipids and phospholipid-binding proteins like β2-GPI but also cell-surface molecules such as annexin A2, apolipoprotein E receptor 2, toll-like receptors, interferon pathways, and the complement system (Fig. 1). The role of C4d in thrombotic microangiopathy (TMA) and SLE patients with positive aPLs was reported [88]. A recent study showed renovascular endothelial activation of mammalian target of rapamycin complex (mTORC) pathway in APS patients resulting in intimal hyperplasia [18].

Clinical Manifestations

Multiple organ systems are affected by APS. Table 3 depicts the clinical manifestations of the condition.

Catastrophic APS is a life-threatening complication of APS characterized by rapid microvascular thrombosis in multiple organs. Diagnostic criteria are the same as in adults [37]. Microangiopathic antiphospholipid-associated syndrome is defined as co-existence of aPLs and TMA in which the pathogenic role of aPLs is controversial. Pediatric HUS and SLE patients with microangiopathic antiphospholipid-associated syndrome have been reported [10, 61].

Renal Involvement

While data is limited, the kidneys may be involved in both primary and secondary forms of APS. The disease may affect any part of the renal vasculature, from large vessels to glomerular capillaries. Renal artery thrombosis or stenosis, renal vein thrombosis, hypertension, APS nephropathy (APSN), chronic kidney disease (CKD), and renal allograft thrombosis may be seen.

The international Ped-APS registry consisting of 121 children reported 1 patient each with renal vein, renal artery, and mixed (artery and vein) thrombosis and 2 patients with renal thrombotic microangiopathy. Almost 35% of patients with secondary APS had lupus nephritis and 5% of patients with primary APS had renal involvement [5]. Ma et al. [57] reported 58 pediatric patients with APS, among which 40 had SLE-related APS with 65% (26/40) lupus

Antiphospholipid nephropathy

nephritis. In the same study, there were two patients who experienced renal vein thrombosis. A study from North America on 22 children with APS reported no renal thrombotic events; of 8 patients with secondary APS, 3 had features of glomerulonephritis [70]. A Mexican study of 32 pediatric patients with APS did not reveal any renal manifestations [104].

Antiphospholipid Syndrome-Associated Nephropathy

The exact prevalence of APSN is not known. Performance of renal biopsies is a challenge to most clinicians due to bleeding risk related to accompanying thrombocytopenia and positive aPLs.

Nephropathy of APS may have different clinical presentations as nephritic or nephrotic syndrome and acute or chronic conditions. For years TMA has been the well-described pathology in biopsies of primary APS patients. Recent insights showed that other pathologies like fibrous intimal hyperplasia or focal cortical atrophy can also be seen. Membranous nephropathy and proliferative glomerulonephritis in primary APS are other examples [90]. In the Ped-APS registry, renal biopsies of three patients with secondary APS showed TMA findings [5]. Focal proliferative glomerulonephritis and pauci-immune necrotizing crescentic glomerulonephritis have also been described in pediatric primary APS patients [15, 65].

It should be kept in mind that TMA seen in APSN is a non-specific lesion, which can be seen in other diseases like thrombotic thrombocytopenic purpura and atypical HUS. Careful assessment is crucial to rule out these critical diagnoses.

Lupus Nephritis (LN) and aPLs

A cross-sectional study of children with SLE from the CARRA registry reported that the presence of aPLs significantly increased the thrombosis risk [30]. A prospective study in 56 children with SLE revealed that aPL-positive children had three times higher risk of organ damage [28]. Another study on 150 SLE patients (44 patients <15 years of age) found that 34% of the patients had APSN and APSN was associated with HT, acute renal failure, persistent proteinuria, severe LN histology (Class 3 and 4), and end-stage renal disease (ESRD) [21].

Catastrophic APS and Kidneys

The pediatric CAPS registry including 46 patients showed 63% of patients had kidney manifestations mainly as renal failure, arterial HT, and proteinuria. Compared to adults, prevalence of renal involvement wasn't significantly different in children (74.2 vs. 63%) [9].

Tektonidou et al. evaluated biopsies of APSN patients and found acute lesions to be more common in CAPS than in primary APS and SLE-APS; chronic lesions like fibrous intimal hyperplasia and focal cortical atrophy were found in similar frequencies among the three groups [97].

Antiphospholipid Syndrome and End-Stage Renal Disease (ESRD)

Little is known about aPLs and overall risk of CKD. In adults CKD incidence ranged between 28–60% in primary and 16–54% in SLE-related APS [27]. In children there are few anecdotal case reports on CKD and ESRD associated with APS [15, 73]. The Ped-APS registry and APS series from different parts of the world did not report any ESRD among their study populations [5, 57, 70, 104]. New studies with broader timescales to explore the long-term renal outcomes are needed.

Among adult patients on hemodialysis (HD), aPL prevalence was found to be high and associated with thrombosis [14]. Renal transplantation in APS carries a high-risk for TMA development, often quite severe. Evidence suggests patients with aPLs have increased risk of early graft loss due to thrombosis of graft vessels or TMA [17]. A recent study on transplant patients showed aCLs increased the risk of estimated glomerular filtration rate decline in 1st year posttransplantation [34].

Treatment

There is limited data on the optimal treatment for pediatric APS. Most of our knowledge is extrapolated from adult studies, and recommendations are mainly expert opinions. The main aims are preventing, treating thrombosis, and preventing recurrence. Treating the underlying disease in secondary APS forms and balancing the potential side effects of therapeutics are other important goals. In healthy children with aPLs, antibodies are usually low-titer, transient, and clinically insignificant; therefore no treatment or prophylaxis is necessary (Table 4).

Children with autoimmune diseases have chronic inflammation as an extra pro-thrombotic risk; therefore the SHARE initiative suggested use of anti-platelet dose aspirin in addition to hydroxychloroquine in children with aPL(+) SLE [39].

Treatment of acute thrombosis in APS is the same as in other diseases and needs consultation with pediatric hematology. A loading dose of unfractionated heparin, followed by its maintenance, is the traditional method. Due to ease of administration, predictable dose-response, and less need for monitoring, low molecular weight heparin (LMWH) is also being considered [58]. After a treatment period with LMWH, children are transitioned to warfarin. In high-risk thrombosis cases, thrombolytic therapy should be cautiously administered. For children, bleeding risks during play and sports should be sought while treatment planning.

Currently new agents with less need for monitoring and side effects are being tested. Direct

Table 4 Recommendations for thromboprophylaxis in children with aPLs/APS

1. Primary thromboprophylaxis
In asymptomatic patients with aPL positivity:
Control of pro-thrombotic risks; smoking, obesity, hyperlipidemia, estrogen-containing oral contraceptives.
In patients with SLE and positive aPLs:
Hydroxychloroquine and anti-aggregant dose aspirin [39]
2. Secondary thromboprophylaxis
No treatment when aPLs disappear [39]
Continue warfarin in persistent aPL positivity, target INR:2-3 [32], target higher INR, or consider other therapeutics if thrombosis recurs [39]
Add aspirin to anticoagulant therapy when history of arterial thrombosis [39]

Note: aPL, antiphospholipid antibody; APS, antiphospholipid syndrome; INR, international normalized ratio; SLE, systemic lupus erythematosus thrombin inhibitors (dabigatran), factor Xa inhibitors (apixaban, rivaroxaban), non-warfarin/heparin anticoagulants, hydroxychloroquine, statins, B-cell inhibitors, complement inhibitors, and peptide therapies are some examples. An adult study compared rivaroxaban and warfarin in APS patients with/without SLE and showed this new agent could be a safe alternative in APS patients with venous thrombosis history [23]. Subsequent study comparing rivaroxaban and warfarin in high-risk patients with APS showed significantly higher rate of thromboembolic events in the rivaroxaban arm and consequently, oral anticoagulants are not recommended in APS patients with triple aPL positivity and arterial thrombosis [76, 98].

Treatment of CAPS

There aren't any pediatric guidelines for CAPS treatment. The literature emphasizes the importance of prompt and aggressive treatment. General approach involves anticoagulation for TMA and immunosuppression to control the cytokine storm. The SHARE initiative recommended prompt use of combined anticoagulants, steroids, and plasma exchange with/without intravenous Ig [39]. Treatment of inciting factors, most commonly the infections, is of critical importance.

Rituximab may also be considered. In the CAPS registry, 20 patients were treated with rituximab as first- or second-line therapy and the majority benefited [8]. Eculizumab was also effectively used for CAPS [106].

Treatment of APSN

There is no consensus on the optimal treatment of APSN. In general it is the same as for APS. Patients with APSN who meet the APS criteria should receive the standard anticoagulatory treatment. In adult APSN with SLE hydroxychloroquine and immunosuppressive treatment is advised [96]. In APS patients with membranous nephropathy, prophylactic anticoagulation should be given due to high thrombosis risk. Hypertension and proteinuria are commonly seen in APSN; therefore angiotensin-converting enzyme inhibitors should be considered. The use of novel oral anticoagulants has not been studied in APSN.

Eculizumab has been successfully used in the posttransplant period of aPL-positive patients with recurrent TMA [40]. Studies showed that rituximab had some effect on renal lesions [31]. Sirolimus (mTOR inhibitor) in transplant patients resulted in longer survival in graft function via decreasing vascular cellular proliferation, inhibition of fibrous intimal hyperplasia, and chronic lesions [18]. However long-term safety data are needed for both agents.

In HD patients with aPLs, anticoagulants may increase the arteriovenous graft survival; however taking the bleeding risk into account, it is advisable to anticoagulate only patients with recurrent graft thrombosis. Perioperative anticoagulation during transplantation may protect from graft failure in patients with aPLs or APS; however thrombosis might still occur.

Anti-glomerular Basement Membrane Disease

Definition

Anti-glomerular basement membrane (anti-GBM) disease is an autoimmune disease in which autoantibodies directed against the noncollagenous-1 (NC1) domain of the α3-chain of collagen type IV affect the kidneys and lungs, resulting in rapidly progressive glomerulonephritis and/or pulmonary disease [7, 38]. Goodpasture syndrome and Goodpasture disease are older terms used synonymously for anti-GBM disease, but also for the clinical constellation of glomerulonephritis and pulmonary hemorrhage (pulmonary renal syndrome), regardless of the underlying pathogenesis.

Epidemiology

Anti-GBM disease is uncommon in adults and extremely rare in children. It is estimated to occur in less than two cases per million population, even less in children – one case per two million population [19, 59]. It accounts for 1–5% of all types of glomerulonephritis and 10–20% of crescentic glomerulonephritis but is a rare cause of end-stage renal disease (ESRD) [49, 95].

In adults, the first peak occurs in young men aged 20–30 years, and the second one in those aged 50–70 years, with men and women equally affected. In children, anti-GBM disease has been reported in all ages, with a peak incidence at 17 years of age [12, 100].

Etiology

Anti-GBM disease results from environmental insults in a person with a genetic predisposition. An exact trigger has not been identified for the development of anti-GBM antibodies, but when they do develop, circulating antibodies can cause renal and/or pulmonary disease. These are usually of the IgG class, with predominant IgG1 and IgG3 subclasses [87]. They are typically polyclonal, but rare cases of monoclonal antibody derived anti-GBM disease have also been described [75]. Antibodies against the α3-chain of collagen type IV can also be detected in healthy individuals, but these have a different IgG subclass distribution, with lower titer and avidity, probably representing natural autoantibodies [24].

An increased genetic susceptibility to Goodpasture syndrome can be seen in humans with certain human leukocyte antigen (HLA) subtypes, most notably HLA-DR15 and HLA-DR4 [77]. While the expression of the α3-chain of collagen type IV is highest in the glomerular and alveolar basement membrane, these antibodies predominantly cause symptoms derived from these two organ systems. However, not all patients with renal also develop pulmonary symptoms and vice versa, even though they all appear to have similar autoantibodies against the α3-chain of collagen type IV [44]. It seems that prior pulmonary and kidney injury/triggers are needed to “expose” the antigens in the glomerular and alveolar basement membranes. Possible triggers of anti-GBM disease, such as pulmonary infections, smoking, hydrocarbon solvents, lung cancer, lithotripsy, ureteral obstruction, membranous nephropathy, and ANCA-associated glomerulonephritis, have been described. In addition, immune dysregulation, namely, hematopoietic cell transplantation, alemtuzumab, checkpoint inhibitors, T-cell large granular lymphocyte leukemia, common variable immunodeficiency, and HIV, also appear to predispose to anti-GBM antibody generation and anti-GBM disease [80].

Autoreactive T-cells, in addition to enhancing B-cell function and antibody production, may have a direct causative role in glomerular and alveolar injury. It was shown that T-cells isolated from patients with anti-GBM disease, but not from controls, react against the α3-chain of collagen type IV and play a role in crescent formation [64].

Clinical Presentation

Most patients with anti-GBM disease present with systemic complaints and clinical features of renal and/or pulmonary disease; other organ involvement is also possible.

Renal manifestations can vary widely, from hematuria and proteinuria to a clinical picture of rapidly progressive glomerulonephritis with rapidly progressive renal failure, oliguria, volume overload, edema, and severe hypertension.

Pulmonary symptoms may or may not precede renal symptoms by weeks or months and appear most commonly with hemoptysis, which can be so profound as to cause respiratory failure and death, or can only be occult and lead to anemia and iron deficiency.

Systemic complaints and signs can be the initial presentation of anti-GBM and consist of symptoms such as malaise, weight loss, fever, and arthralgia. These are usually experienced for only a few weeks, and when present for a longer period, suggest that a patient is double positive for anti-GBM and antimyeloperoxidase (MPO-ANCA) and has features of concurrent vasculitis [26, 49, 80].

Other organ involvement is rare, but not exclusive. A case report of a teenager with cerebral vasculitis with confusion, aphasia, and seizures has been reported [36].

Double-positive anti-GBM and ANCA-associated disease has been described in 10–50 percent of patients with anti-GBM disease [53]. These patients tend to have a higher rate of relapses, a generally worse pattern of disease and the need for early treatment in order to achieve a better outcome [60], and poorer recovery of renal function, potentially linked to greater glomerular damage due to the presence of both antibodies [53].

There is up to 50 percent of recurrent linear IgG staining in the transplant, but most patients remain asymptomatic [50, 59]. The target GBM antigens for recurrent anti-GBM disease are the noncollagenous-1 (NC1) domain of the α3- and α5-chains of collagen type IV. Similar findings can be found in Alport posttransplant anti-GBM nephritis, where anti-GBM syndrome is mediated by the deposition of alloantibodies to the α5-chains of collagen type IV in response to the "foreign-transplanted" collagen antigen normally absent in patients with Alport syndrome but present in the renal allograft [42]. Most patients remain asymptomatic, while patients with clinically evident recurrence of anti-GBM disease after transplantation can have a wide range of symptoms, the onset of which can range from months to years posttransplant.

Diagnosis

Anti-GBM disease should be suspected in any patient with acute/subacute nephritic syndrome, particularly if it is rapidly progressive and/or accompanied by alveolar hemorrhage. It should also be suspected in a patient with isolated alveolar hemorrhage; patients with features of systemic disease; patients with nephrotic syndrome who develop a rapid decline of renal function, patients with proteinuria, hematuria, or mild renal insufficiency with linear IgG staining of the GBM on kidney biopsy; and kidney transplant recipients with underlying Alport syndrome who present with acute glomerulonephritis or graft failure. The diagnosis is thereafter confirmed by the demonstration of anti-GBM antibodies in the serum or the kidney/lung [49]. If not contraindicated, renal biopsy should be performed, since the accuracy of serological testing is variable and, in addition, it provides additional and important information regarding the activity and chronicity of renal involvement that may help guide therapy.

In general, a direct enzyme-linked immunoassay (ELISA) with purified or semi-purified Goodpasture syndrome antigens is the most commonly used assay. False-positive and false-negative results may occasionally occur [55]. Sensitivity ranges from 63–100% and depends on the commercial kit used.

Western blot, considered as a reference test, is used in some cases to confirm the antigenic (NC1 – domain of the α3-chain of collagen type IV) specificity of anti-GBM antibodies [49].

Indirect immunofluorescence is a rarely performed historical test that requires an experienced renal pathologist. It is performed by incubating normal renal tissue with the patient's serum and then treating it with fluorescein-labeled anti-IgG. The test has a high false-negative rate, and the difficulty in detecting a low titer of anti-GBM antibodies explains why this technique is no longer recommended [80].

In addition to anti-GBM antibody testing, testing for antineutrophil cytoplasmic antibodies (ANCA) should be performed in all patients who are diagnosed with anti-GBM disease, since the clinical course and treatment plan may differ in double-positive patients [7, 53].

As neither method for anti-GBM antibody detection is completely reliable, a kidney biopsy is always recommended unless contraindicated. Light microscopy most commonly shows crescentic glomerulonephritis, while a virtually pathognomonic finding of bright linear IgG deposits along GBM is seen by immunofluorescence. In rare cases, the antibody may be IgA or IgM [6].

Pulmonary biopsy in not necessary when a kidney biopsy and serological tests have already confirmed the diagnosis of anti-GBM disease but can be done in an isolated pulmonary disease. Pulmonary histopathology often shows a linear deposition of IgG, but this finding is not as constant as in a kidney biopsy [80].

Differential Diagnosis

Other causes of acute glomerulonephritis associated with pulmonary hemorrhage (pulmonary renal syndromes) and other renal disorders in which linear IgG staining may be seen in the glomeruli on a kidney biopsy should be considered in the differential diagnosis of anti-GBM disease.

Pulmonary hemorrhage can be seen with other acute glomerulonephritis when complicated by pulmonary edema or lung involvement in systemic vasculitis (ANCA-positive, IgA vasculitis, and mixed cryoglobulinemia syndrome) and systemic lupus erythematosus. Antiphospholipid syndrome and pulmonary infection with concomitant acute kidney injury may also present, for example, pulmonary renal syndromes. Differentiation between these disorders is difficult on the basis of a clinical picture alone, and serological testing and kidney biopsy are required to establish the diagnosis.

Linear IgG staining on kidney biopsy may be seen in diabetic nephropathy and fibrillary glomerulonephritis, though staining is rarely as strong as with anti-GBM disease, and there are several other issues on the basis of which these two entities can be easily distinguished from anti-GBM disease (circulating anti-GBM antibodies are absent in both disorders, crescents are not seen in diabetic nephropathy, characteristic fibrils are seen on electron microscopy in fibrillary glomerulonephritis) [80].

Treatment

Recommendations for the treatment of anti-GBM disease in children are mainly based on studies in adults. Early diagnosis is vital in terms of ability to recover renal function [79, 80]. In addition to early diagnosis, the degree of initial renal impairment is also a very important prognostic factor. It was reported that avoidance of end-stage renal disease is very rare in patients who require dialysis within 72 h, in particular if they have crescents involving all glomeruli. On the other hand, prevention of end-stage renal disease can usually be achieved in less severe cases, although some do progress [52]. KDIGO adult guidelines therefore recommend avoiding immunosuppressive treatment in patients who are dialysis-dependent on presentation or who have 100% crescents in an adequate biopsy sample, in the absence of pulmonary hemorrhage [72]. Nevertheless, more than 50% of nephrology centers do not follow this recommendation and still treat these patients [52, 53, 63]. The inability to consistently and accurately identify the dialysis-dependent patient who may recover renal function has led some investigators to nevertheless treat patients with very acute disease, young patients who can tolerate aggressive immunosuppression better, and patients with anti-GBM antibody disease who are also double-positive for ANCA and have clinical signs of systemic vasculitis [53].

The treatment of choice in anti-GBM disease is intensive plasmapheresis [52, 56, 79]. Plasmapheresis is aimed to remove circulating antibodies, while the purpose of immunosuppression is to reduce their production. Plasmapheresis must be accompanied by aggressive immunosuppression consisting of corticosteroids and cyclophosphamide [25]. An alternative, rituximab or mycophenolate mofetil, has also been tried [68, 94].

The optimal duration of therapy is unknown. Anti-GBM antibody titers are monitored regularly (every 1–2 weeks until they are negative on two occasions), and treatment with plasmapheresis is stopped or prolonged depending on their levels and the patient's clinical condition [79]. Once a remission of the disease is achieved, maintenance with low-dose prednisone and azathioprine should be continued for 6–9 months.

A rather novel approach in treating anti-GBM disease is immunoadsorption, which can remove pathogenic IgG from circulation and does not require plasma infusions as in plasmapheresis; it may be/prove effective in anti-GBM disease [11, 29].

Experimentally, the development of crescentic glomerulonephritis was completely prevented in a rat model of anti-GBM antibody disease, with a blockade of CD28-B7, a costimulatory pathway for T-cell activation, by the fusion protein CTLA4Ig [82].

Outcome

Before the era of immunosuppressives such as corticosteroids and before the era of plasmapheresis, most patients with anti-GBM disease died of pulmonary hemorrhage or renal failure. The current therapeutic approach has reduced mortality among adults to less than 20% and in children to around 30% [78, 86].

Outcome seems to be directly correlated with initial renal impairment and the percentage of crescents on the initial kidney biopsy specimen. Despite potentially serious lung hemorrhage, there is virtually no residual pulmonary deficit or fibrosis when patients recover [49]. Recurrence of the disease with antibody production is possible, but rare, as it occurs spontaneously or is precipitated by infection or exposure to a toxic agent [49, 62]. Renal transplantation can initiate antibody production [48, 50]. Patients with anti-GBM and ANCA antibodies present with a better renal outcome but may experience more relapses [53].

IgG4-Related Disease

Introduction

IgG4-related disease (IgG4-RD) is a multi-organ fibro-inflammatory disease, including autoimmune pancreatitis (AIP), Mikulicz' disease, sclerosing cholangitis, respiratory disease, thyroid disease, lymphadenopathy, periaortitis, retroperitoneal fibrosis, and kidney disease [92]. Hamano et al. were the first to note elevation of serum IgG4 levels among patients with AIP, in concert with predominant infiltration of IgG4-bearing plasma cells in the pancreatic tissue [41]. Subsequently, Kamisawa et al. demonstrated increases of IgG4-bearing plasma cells in a variety of organs in patients with AIP and proposed the concept of IgG4-related autoimmune disease [45].

The prevalence of IgG-RD has been unclear, because this disease entity was seldom recognized until recently and integrated data on the involvement of different organs is absent. IgG4-RD predominantly occurs in elderly males (male-female=2:1, 58.2 ± 14.5 years), and reports of pediatric cases were rare. A systematic literature search found 25 cases of IgG4-RD in pediatric patients, and the youngest one was a 3-year-old female with cholangitis [46]. The review showed female predominance, and orbital disease was associated in about half of the pediatric patients. Comprehensive view of IgG4-RD as a systemic disease has been accepted among different specialties, and several important collaborative works have been reported [93, 101].

The clinical features of IgG4-RD are varied, depending on the affected organs and the degree of activity and stage of each organ's involvement. IgG4-RD could be divided into four clinical features, including pancreato-hepato-biliary disease, retroperitoneal fibrosis and/or aortitis, head and neck-limited disease, and classic Mikulicz syndrome with systemic involvement. Organ involvement might not occur simultaneously, and it often appears in a metachronous manner.

Is IgG4-RD an Autoimmune Disease?

IgG4-RD has been considered as an immune-mediated disease, because AIP has several immune-related features, i.e., hypergammaglobulinemia, presence of various autoantibodies, lymphoplasmacytoid infiltration, and effectiveness of steroid [84]. Immunological characteristics, typically oligoclonal expansion of IgG4-positive plasmablasts, appear in the circulation and the tissue, and circulating plasmablasts and activated B cells frequently revealed somatic hypermutation, indicating an adaptive immune response driven by an antigen in IgG4-RD. In addition, recent report revealed activation of T follicular helper cell (Tfh) and synthesis of Th2 cytokines in IgG4-RD, suggesting autoimmune pathogenesis [51]. Alternative pathogenesis of IgG4-RD may be allergy, because of Th2 activation [105]. Indeed, one third of IgG-RD patients have a history of allergic diseases, such as asthma, rhinitis and atopic dermatitis, and hyperproduction of IgG4 or eosinophilia. The mechanism of IgG4-RD may be based on the complex immune-related responses. Typically, a direct role of IgG4 and/or IgG4-bearing cells in tissue damage and the roles of lymphocyte activation linking to tissue fibrosis have not been identified.

IgG4-Related Kidney Disease

IgG4-related kidney disease (IgG4-RKD) reveals characteristic clinical, radiological, and pathological features, being the main basis of its diagnosis.

Clinical Features

Like IgG4-RD in general, IgG4-RKD frequently occurs in elderly males. The mean age was 64 years, and 73% of the patients were male [47]. Pediatric cases with IgG4-RKD were very rare and only a few patients were reported. Unfortunately, detailed description as IgG4-RKD has not been given in the literatures [46]. Either elevation of serum IgG levels, hypocomplementemia, or high IgE levels is associated with IgG4-RKD. The clinical features of IgG4-RKD largely reflect the characteristic tubulointerstitial nephritis (TIN). The onset of nephropathy is rather insidious, and the disease can often be identified as a subacute or chronic renal dysfunction. The levels of proteinuria are generally mild and hematuria is at minimal levels. As is typical in chronic TIN, β2-microglobulin and N-acetyl-β-D-glucosaminidase are useful for the diagnosis of IgG4-RKD. In cases with nephrotic syndrome, albeit rare, it may be membranous nephropathy or fortuitous association of other kidney diseases such as minimal change disease. IgG4-RKD is often progressive and leads to chronic renal failure, if the response to therapy is poor. On the other hand, there are cases with spontaneous remission.

Radiological Findings

Radiological examination by contrast-enhanced computed tomography (CT) and magnetic resonance imaging has great value for the diagnosis. Radiological findings reveal various features, i.e., bilateral kidney swelling, poorly enhanced wedge- or round-shaped mass, or multiple nodular lesions (Fig. 2a). A single space-occupying shadow has been misdiagnosed as kidney tumor and surgically removed.

Kidney Pathology

Kidney pathology is an important diagnostic basis and provides clues to understand the pathophysiology of progressive IgG4-RKD. It reveals characteristic tubulointerstitial nephritis as follows (Fig. 2b–f): (1) clear border with adjacent preserved parenchyma (Fig. 2b); (2) plasma cell-rich infiltration with predominant IgG4-bearing cells (Fig. 2c, e, f); (3) lack of neutrophil infiltration and tubulitis; (4) fibro-inflammatory changes in the cortex, the medulla, and the renal capsule; (5) a characteristic pattern of interstitial fibrosis, called “bird’s eye pattern” or “storiform fibrosis” (Fig. 2d); and (6) immune deposition along the tubular basement membrane, IgG4 and/or IgG1 and C3 and C1q [102]. Sjögren’s syndrome, anti-neutrophil cytoplasmic antibody (ANCA)-associated vasculitis, and interstitial lupus nephritis are similar to IgG4-RKD and need discrimination. Membranous nephropathy (MN) is another kidney disease associated with IgG4-RD, in patients with nephrotic syndrome. Immunofluorescence reveals a granular pattern of IgG4 deposition along the glomerular basement membrane (GBM). Anti-M-type phospholipase A2 receptor antibody (antigen of idiopathic MN) is useful to discriminate IgG4-related MN and IgG4-RD with idiopathic MN.

Diagnostic Criteria

Diagnosis of IgG4-RKD is not always easy, because of clinical and pathological heterogeneity and because the diagnosis is made by several inclusion criteria. The American College of Rheumatology/European League Against Rheumatism classification criteria for IgG4-RD recommended the following inclusion criteria for IgG4-RKD [101]: (1) hypocomplementemia with low serum levels of C3, C4, or both; (2) renal pelvic wall thickening, either unilateral or bilateral, usually without severe stenosis or luminal irregularity; and (3) low-density areas in both renal cortices seen only on contrast-enhanced CT and usually patchy or round-shaped in appearance. The diagnostic criteria of IgG4-RKD in 2020 had a sensitivity of 90.9% and specificity of 90% (Table 5) [85]. It should be noted that ANCA is often positive in cases with IgG4-RD,

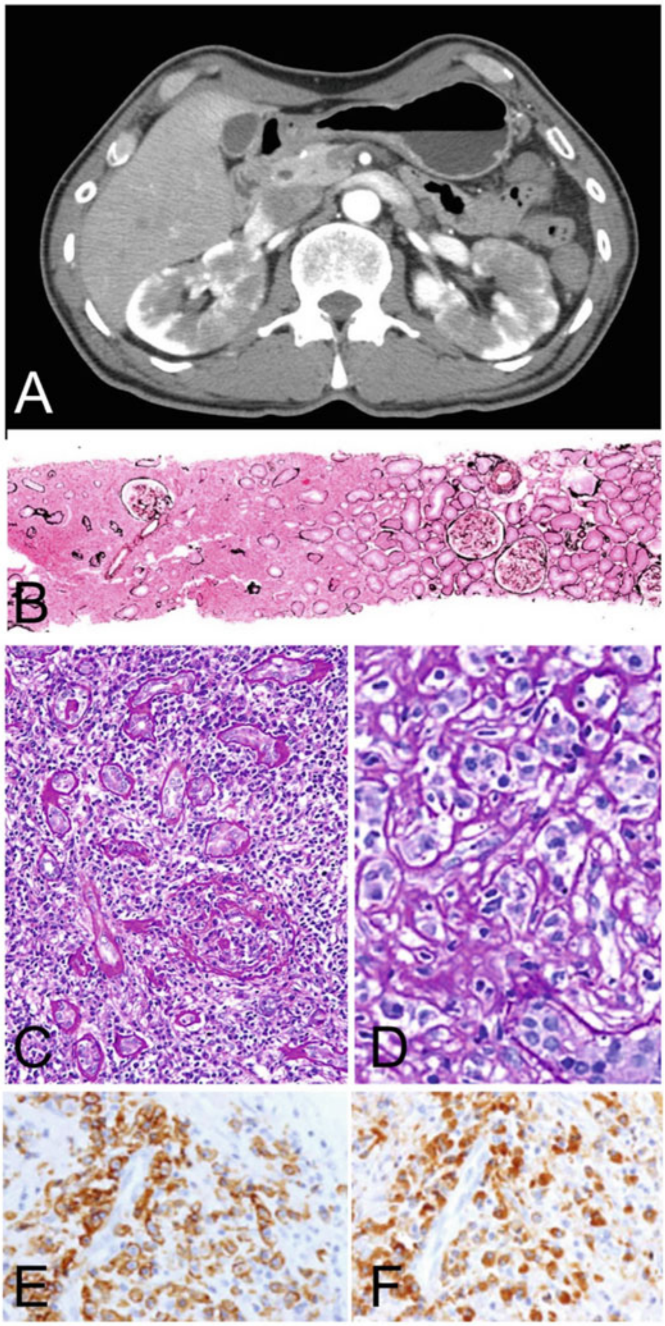

Fig. 2 Radiological and histological characteristics of IgG4-RKD. (**a**) Contrast-enhanced computed tomography showing multiple poorly enhanced lesions in the bilateral kidney. (**b**) Kidney biopsy sample with PAM stain reveals that tubular loss with intensive inflammatory infiltrates is clearly demarcated by the neighboring preserved renal parenchyma. (**c**) Larger magnification view of renal cortex showing plasma cell-predominant infiltration. (**d**) Characteristic pattern of tubulointerstitial fibrosis, called "bird's eye" or "storiform" pattern of fibrosis (**e**). Immunohistochemistry of IgG (**e**) and IgG4 (**f**). Note that IgG4-bearing cells are the major component of IgG-positive plasma cells. (**a**, **b**, **e**, and **f** were from reference 4 with permission)

and eosinophilic granulomatous polyangiitis and granulomatosis with polyangiitis occasionally fulfill the criteria for IgG-RKD.

Treatment

Good response to steroids is a distinct characteristic of IgG4-RD that helps the diagnosis. Steroids

Table 5 Diagnostic criteria for IgG4-related kidney disease (IgG4-RKD) 2020

1. Presence of some kidney damage; abnormal urinalysis or urine marker(s) or decreased kidney function with either elevated serum IgG level, hypocomplementemia, or elevated serum IgE level
2. Abnormal renal radiological findings:
(a) Multiple low-density lesions on enhanced computed tomography
(b) Diffuse kidney enlargement
(c) Hypovascular solitary mass in the kidney
(d) Hypertrophic lesion of renal pelvic wall without irregularity of the renal pelvic surface
3. Elevated serum IgG4 level (IgG4 > 135 mg/dl)
4. Histologic findings in the kidney
(a) Dense lymphoplasmacytic infiltration with infiltrating IgG4-positive plasma cells >10/high power field (HPF) and/or IgG4/IgG-positive plasma cells >40%
(b) Characteristic fibrosis surrounding nests of lymphocytes and/or plasma cells
5. Extra-renal organ(s):
(a) Dense lymphoplasmacytic infiltration with infiltrating IgG4-positive plasma cells >10/HPF and IgG4/IgG-positive plasma cells >40% in extra-renal organ(s)
(b) Imaging or clinical findings in extra-renal organ(s); one of the following items;
1. Bilateral lacrimal gland swelling
2. Bilateral submandibular or parotid gland swelling
3. Imaging findings compatible with type 1 autoimmune pancreatitis
4. Imaging features of retroperitoneal fibrosis

Definite: Any of the below combinations
1 + 3 + 4a + 4b; 2 + 3 + 4a + 4b; 2 + 3 + 5a; 1 + 3 + 4a + 5a or 5b; 2 + 3 + 4a + 5b
Probable: Any of the below combinations
1 + 4a + 4b; 2 + 4a + 4b; 2 + 5a; 2 + 3 + 5b
Possible: Any of the below combinations
1 + 3; 2 + 3; 1 + 4a; 2 + 4a; 2 + 5b
Appendix 1. Clinically and histologically, exclusion of the following diseases should be considered: ANCA-associated vasculitis, multicentric Castleman's disease, malignant lymphoma, and extramedullary plasmacytoma. 2. Radiologically, exclusion of the following diseases should be considered: malignant lymphoma, urinary tract carcinoma, renal infarction, and pyelonephritis (rarely, granulomatosis with polyangiitis, sarcoidosis, and metastatic carcinoma)

are also known to be effective in IgG4-RKD, being the first choice, and early steroid immediately after the diagnosis is important in the treatment of IgG4-RKD. Although initial effects of steroid are favorable, tapering or stopping steroid often induces recurrence. Hypocomplementemia and high serum IgG4 are paralleled with steroid treatment, being useful markers for therapeutic effects. Several reports of IgG4-RD described usage of azathioprine, tacrolimus, mycophenolate mofetil, and abatacept in the cases with unfavorable response to the steroid; however, their safety and effectiveness have not been well established.

Cryoglobulinemic Vasculitis

Cryoglobulinemic vasculitis is an immune complex-mediated inflammation of the small- and medium-sized blood vessels, leading to skin and internal organ involvement, including the kidney. It is characterized by the presence of cryoglobulins, which are immunoglobulins that precipitate when the temperature falls below 37 °C and re-solubilize on warming. Cryoglobulinemic vasculitis rarely occurs in isolated, primary form and is usually associated with other diseases such as infections, autoimmune diseases, and lymphoproliferative disorders [83].

Definition and Classification

Cryoglobulinemia refers to the presence of cryoglobulins in serum. Based on the Brouet classification [13], three major groups of cryoglobulins are recognized according to the clonality and type of immunoglobulins:

- Type I cryoglobulins consist of single, monoclonal immunoglobulin, usually IgM and sometimes IgG or IgA
- Type II cryoglobulins are a mixture of monoclonal IgM and polyclonal IgG; the monoclonal IgM usually have rheumatoid factor activity
- Type III cryoglobulins are a mixture of polyclonal IgM and IgG

Type I cryoglobulinemia is associated exclusively with B-cell proliferative diseases. Type II and III cryoglobulinemias are classified as "mixed cryoglobulinemias" because they consist of both IgG and IgM components. Both type II and type III mixed cryoglobulinemias are associated with hepatitis C virus (HCV) infection, autoimmune diseases, or B-cell lymphoproliferative diseases.

The presence of cryoglobulins can be detectable in the serum of patients with several inflammatory conditions, but it remains asymptomatic in most of them. The term "cryoglobulinemic vasculitis" is used to define the presence of cryoglobulins and the clinically apparent disorder with cutaneous vasculitis, nephritis, and other organ involvement [81]. According to the 2012 International Chapel Hill consensus nomenclature, cryoglobulinemic vasculitis is included among the non-antineutrophil cytoplasmic antibody (ANCA)-associated small vessel vasculitides [43].

Cryofibrinogenemia is a rare form of cryopathy defined by the presence of a cold-induced precipitate found in plasma, which is characteristically composed of fibrinogen, fibrin, fibronectin, and fibrin degradation products [22].

Epidemiology

Cryoglobulinemic vasculitis is a rare disease with less than 5 cases per 10,000 individuals, but the prevalence is significantly higher in some geographical regions such as the Mediterranean Basin. The most common cause is chronic infection with HCV which globally affects more than 184 million individuals. Mixed cryoglobulinemia was detected in up to 60% of patients with HCV infection, but only 5% of individuals with HCV infection develop cryoglobulinemic vasculitis. About 10–20% of cases of mixed cryoglobulinemia are not associated with HCV infection and are associated with other infections (hepatitis B virus, HIV, bacterial endocarditis), autoimmune diseases (Sjögren's syndrome, systemic lupus erythematosus, dermatomyositis), and malignancies (B-cell lymphoproliferative diseases). Essential or idiopathic cryoglobulinemia represents approximately 10% of cases of mixed cryoglobulinemia [83]. The frequency of cryoglobulinemia in pediatric population represents about 15–20% of adult cases [54].

Etiopathogenesis

Cryoglobulins are generated by persistent immune stimulation caused by chronic infections or autoimmune diseases and in the case of malignancies by the clonal expansion of B cells. HCV is able to infect both hepatocytes and B cells causing polyclonal B-cell proliferation as well as B-cell transformation with predominantly IgM-producing memory B cells and increased expression of lymphomagenesis-related genes critical for somatic hypermutation and prevention of B-cell apoptosis. Chronic antigenic stimulation by HCV infection leads to widespread production of heterogeneous autoantibodies.

Precipitation of cryoglobulins could be triggered by cold exposures and in the case of mixed cryoglobulinemia by the formation of large, complement-bound immune complexes formed by circulating HCV particles, anti-HCV polyclonal IgG, and monoclonal IgM with rheumatoid factor activity. Tissue injury in cryoglobulinemic vasculitis is caused by immune complex-mediated inflammation in small blood vessels and vascular occlusion due to cryoglobulin precipitation in the microcirculation. In cryoglobulinemic glomerulonephritis, there is additional macrophage recruitment to the glomerulus trying to remove deposited cryoglobulins. Ineffective cryoglobulin clearance by phagocytes could further perpetuate glomerular damage [91].

Familial cases of cryofibrinogenemia were found in patients with *TREX1* gene mutation most of whom presented in the childhood age with cold-induced acrocyanosis [74].

Clinical Manifestations

Clinical manifestations of cryoglobulinemia are caused by two principal mechanisms. The first mechanism is hyperviscosity and occlusion of small blood vessels caused by cryoglobulin precipitation. Common manifestations in patients with hyperviscosity syndrome include Raynaud's phenomenon, cold-induced acral ulcers, digital gangrene, livedo reticularis, retinal hemorrhages, blurry vision, epistaxis, headache, confusion, and encephalopathy. These manifestations are common in type I cryoglobulinemia with high cryoglobulin concentrations [81].

The second mechanism is immune complex-mediated vasculitis of small blood vessels, which is common in types II and III mixed cryoglobulinemias. The most common manifestations of cryoglobulinemic vasculitis are cutaneous purpura, arthralgia, arthritis, kidney involvement, and peripheral neuropathy. Flares of cryoglobulinemic vasculitis are often accompanied also by general symptoms such as fever, weakness, and myalgia [81]. Kidney involvement usually displays as isolated proteinuria or hematuria and less commonly as nephritic syndrome or acute kidney failure [71]. Children with cryoglobulinemia more commonly present with fever and musculoskeletal and cutaneous involvement [54].

Diagnosis

The diagnosis of cryoglobulinemic vasculitis requires demonstration of cryoglobulins in association with suggestive clinical vasculitis symptoms. Decreased serum levels of early components of the complement cascade (C4) and raised titers of rheumatoid factor are commonly seen in mixed cryoglobulinemias. The presence of urinary abnormalities (hematuria, proteinuria) and hypertension demonstrate renal involvement and require confirmation by renal biopsy. Renal biopsy usually shows type I membranoproliferative glomerulonephritis with subendothelial IgG, IgM, and C3 deposits, hyaline intraluminal thrombi, and glomerular infiltration by monocytes. Focal, mesangioproliferative, or membranous glomerulonephritis are less frequent and could be associated with underlying systemic autoimmune disease such as SLE [20, 91]. Laboratory testing should include evaluation of autoantibodies (ANA, anti-dsDNA, anti-ENA, aPL, and ANCA) to detect underlying systemic autoimmune disease, infectious workup for viral hepatitis (hepatitis C and B) or other potential infectious causes, and malignancy workup.

Treatment and Outcome

Treatment of cryoglobulinemic vasculitis is adapted according to the underlying mechanism and includes combination of immunosuppressive therapy to reduce immune complex-mediated inflammation, antiviral treatment for underlying HCV infection, and biologic therapy aimed at suppressing B-cell proliferation [33, 69, 83]. Milder manifestations of noninfectious cryoglobulinemic vasculitis such as purpura, livedo reticularis, and non-debilitating neuropathy are treated with low-dose corticosteroids. Cutaneous ulcers, glomerulonephritis, and progressive peripheral neuropathy are treated with corticosteroids and rituximab or cyclophosphamide [35]. Life-threatening manifestations including rapidly progressive glomerulonephritis, pulmonary hemorrhage, mesenteric vasculitis, and CNS involvement are treated with high-dose corticosteroids and plasmapheresis in combination with cyclophosphamide and rituximab [33, 69, 89]. Intravenous immunoglobulin application is contraindicated as it can exacerbate immune complex precipitation leading to multi-organ failure. Symptomatic hyperviscosity requires urgent treatment with plasma exchange [83].

The outcome strongly depends on the underlying condition and complications. Poor prognostic signs in patients with noninfectious cryoglobulinemic vasculitis include renal failure and pulmonary and gastrointestinal involvement [99]. There are no data on the long-term prognosis of pediatric patients with cryoglobulinemic vasculitis.

Conclusion

Nephropathies may occur in relation to several autoantibodies which may target renal-specific autoantigens like in anti-GBM disease or autoantigens of various tissues as in systemic autoimmune diseases. Recent developments in autoantibody detection have increased the reliability and relevance of autoantibody testing and eased the diagnosis of autoimmune nephropathies. Although seen relatively rare in the pediatric age, these diseases cause important morbidity and may lead to end-stage renal disease. Being aware of these rare entities, paying attention to kidney symptoms, and making appropriate investigations will make early diagnosis and prompt interventions possible.

Abstract

Membranoproliferative glomerulonephritis (MPGN) and C3 glomerulopathy (C3G) define a disease pattern characterized by proteinuria, hypertension, and impaired kidney function with a significant risk of disease progression to end-stage kidney disease (ESKD) despite all current treatment efforts. While historically morphological criteria were applied to classify MPGN, recent advances in the understanding of disease pathogenesis with the appreciation of predominant glomerular C3 deposition and the identification of a key role for the complement alternative pathway (AP) resulted in disease reclassification. Today, C3G characterizes a glomerulopathy with predominant C3 deposition. It can be subdivided by electron microscopy into dense deposit disease (DDD) with electron-dense deposits located in the lamina densa of the glomerular basement membrane (GBM), and C3 glomerulonephritis (C3GN) with deposits in subendothelial, subepithelial, and/or mesangial localization. By contrast, cases with coappearance of C3 and immunoglobulins are classified as idiopathic immune-complex MPGN (IC-MPGN). Interestingly, complement mutations and C3 nephritic factor (C3NeF) – an IgG antibody binding to and stabilizing the AP C3 convertase – are found in about 20 and 80% of C3G cases, respectively, but can also be found in IC-MPGN patients. Current treatment recommendations include conservative measures in all cases, and in some immunosuppression with corticosteroids and mycophenolate mofetil (MMF). While milder in children compared to adults, overall prognosis is poor, with roughly 20% of children reaching end-stage kidney disease (ESKD) within 10–15 years. Future treatment strategies are expected to include therapies that block the AP and thereby reduce glomerular C3 accumulation.

Keywords

Membranoproliferative glomerulonephritis · Immune complex glomerulonephritis · C3 glomerulopathy · C3 glomerulonephritis · Dense deposit disease · Complement alternative pathway

Abbreviations

ACEi	Angiotensin-converting enzyme inhibitor
aHUS	Atypical hemolytic uremic syndrome
AMD	Age-related macular degeneration
AP	Alternative pathway (of complement)
aPL	Acquired partial lipodystrophy
ARB	Angiotensin II receptor antagonist
ASO titer	Antistreptolysin O titer
C	Complement
C3G	C3 glomerulopathy
C3GN	C3 glomerulonephritis
C3NeF	C3 nephritic factor
C4NeF	C4 nephritic factor
C5NeF	C5 nephritic factor
CFB	Complement factor B
CFH	Complement factor H

CFHR1-5	Complement-factor-H-related protein 1-5
CFI	Complement factor I
CFP	Properdin
CP	Classical pathway (of complement)
DDD	Dense deposit disease
DEAP-HUS	Deficiency of FHR plasma proteins and FH autoantibody positive HUS
DGKE	Diacylglycerol kinase epsilon
ESKD	End-stage kidney disease
FFP	Fresh frozen plasma
GBM	Glomerular basement membrane
GN	Glomerulonephritis
IC	Immune complex
iC3b	Inactivated C3b
Ig	Immunoglobulin
IRGN	Infection-related glomerulonephritis
LP	Lectin pathway (of complement)
MCP	Membrane-cofactor protein
MLPA	Multiplex ligation-dependent probe amplification
MMF	Mycophenolate mofetil
MPGN	Membranoproliferative glomerulonephritis
NeF	Nephritic factor
NGS	Next-generation sequencing
PMN	Polymorphonuclear leukocytes
RAAS	Renin-angiotensin-aldosterone system
SCR	Short consensus repeat
SNP	Single-nucleotide polymorphism
TMA	Thrombotic microangiopathy

Introduction

Membranoproliferative glomerulonephritis (MPGN)/C3 glomerulopathy (C3G) defines a disease pattern clinically characterized by proteinuria, hypertension, and impaired kidney function with a significant risk of disease progression to end-stage kidney disease (ESKD) in roughly 20% of children within 10–15 years from onset.

From a Morphology to a Pathogenesis-Based Disease Classification

The membranoproliferative pattern of glomerular injury has been recognized as far back as Volhard and Fahr's atlas of glomerular morphology in Bright's disease [1]. MacCallum, Bell, Ellis, Allen, and Jones described lobular and proliferative changes consistent with MPGN in the 1930s through the 1950s [2–6]. But it was not until West et al. described hypocomplementemia in children with a membranoproliferative pattern of glomerular injury that MPGN becomes a "disease" [7]. MPGN was subclassified into type I, type II, and two type III (Burkholder III and Strife/Anders III) [8–11]. Despite the insight by Johnson et al. showing hepatitis C as the cause for more than 80% patients with MPGN type I, nosology expansion continued as pathologists used the term indiscriminately as characteristic of a wide variety of disparate entities (Table 1). As expansion continued, it became clear that MPGN is not a disease, but a pattern of disease [12].

The historical classification has been replaced and is now based on pathogenesis as demonstrated by the presence or absence of immunoglobulins and complement components on renal biopsy: (1) C3 glomerulopathy (C3G) with C3 deposits alone or C3 dominant deposits; (2) immune-complex MPGN (IC-MPGN) with C3 deposits with dominant or codominant immunoglobulins/immune complex deposits; and (3) immune-negative MPGN [13, 14]. These cases are the result of endothelial injury with or without an immune-associated cause including chronic sickle cell anemia, transplant glomerulopathy, etc.

The vast majority of biopsies with an MPGN pattern will have either C3 and Ig deposits or no deposits and are secondary to any of a large number of diseases (Table 1). In rare cases, the underlying etiology of IC-MPGN cannot be determined

Table 1 Causes of secondary membranoproliferative glomerulonephritis (MPGN)

Immunoglobulin mediated
Infectious diseases
Hepatitis B [182], hepatitis C [183], hepatitis E [184], Epstein Barr virus [185], and human immunodeficiency virus [186]

Tuberculosis [190], leprosy [191]
Brucellosis [192], Q fever [193]
Malaria [194], schistosomiasis [195]
Onchocerciasis; filariasis, *Loa loa* infections [196]
Systemic immune diseases
Cryoglobulinemia [197]
Systemic lupus erythematosus [198]
IgA vasculitis [199]
Sjögren syndrome (secondary to cryoglobulinemia) [200]
Hypocomplementemic urticarial vasculitis [201]
Rheumatoid arthritis [202]
X-linked agammaglobulinemia [203]
Neoplasms/dysproteinemias
Plasma cell dyscrasia [204]
Monoclonal gammopathy of unknown significance [205, 206]
Fibrillary glomerulopathy [207]
Immunotactoid glomerulonephritis [208]
Proliferative glomerulonephritis with monoclonal immunoglobulin deposition [209, 210]
Proliferative glomerulonephritis with isolated light chain deposition [211]
MPGN with masked monotypic immunoglobulin deposits [212]
Light-chain and/or heavy-chain deposition disease [213]
Leukemias and lymphomas (with or without cryoglobulinemia) [214, 215]
Bone marrow transplant [216]
Carcinomas, Wilms tumor, and malignant melanoma [217]
Angiofollicular lymph node hyperplasia with or without TAFRO syndrome [218, 219]
Sinus histiocytosis with massive lymphadenopathy [220]
Other
Alpha-1-antitrypsin deficiency with severe liver disease [221]
Gluten-sensitive enteropathy (celiac disease) [222]
Immunoglobulin negative
Thrombotic microangiopathy including drug-induced forms [223]
Sickle-cell disease [224]
Transplant glomerulopathy [225]
POEMS syndrome [226]

TAFRO thrombocytopenia, anasarca, fever, renal dysfunction (or reticulin myelofibrosis), and organomegaly, *POEMS syndrome* polyneuropathy, organomegaly, endocrinopathy, monoclonal gammopathy, and skin changes

and is referred to as "idiopathic IC-MPGN" [15]. However, these cases should be further examined for abnormalities of complement as they may represent C3G with some immunoglobulin deposition.

C3G is the primary focus of this chapter. It is considered a primary complement disease, where complement deposition is the result of defective control of the complement alternative pathway (AP) [16, 17].

Histopathology

C3 Glomerulopathy

Light microscopy: There are four major light microscopy patterns seen in DDD and C3GN including a mesangial proliferative pattern, a membranoproliferative pattern, a crescentic pattern, and an acute proliferative and exudative pattern (Figs. 1 and 2) [18–22]. Vargas et al. provided the first major report detailing the not uncommon finding of numerous polymorphonuclear leukocytes (PMNs) in DDD as well as the crescentic variant of DDD [23].

Immunofluorescence microscopy: Multiple studies have detailed the immunofluorescence

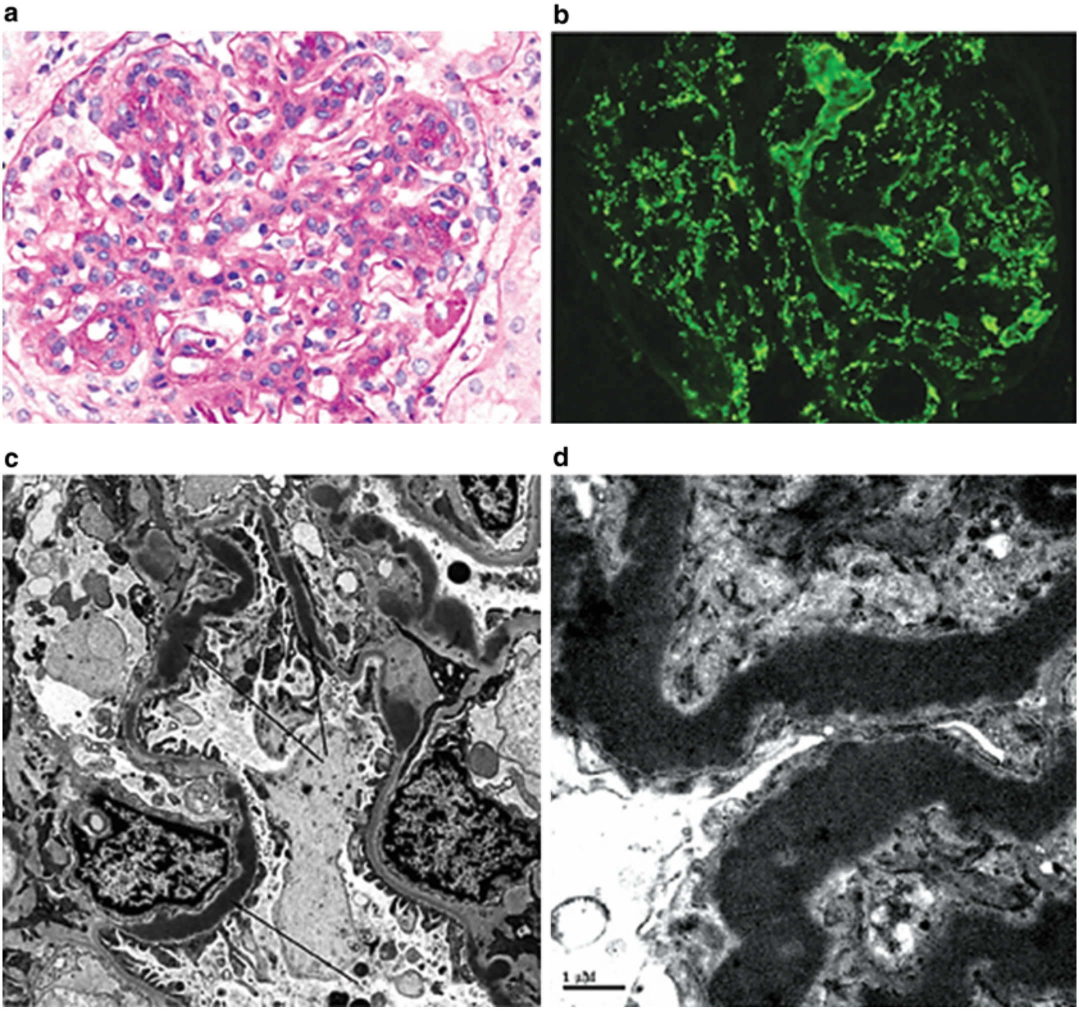

Fig. 1 Dense deposit disease: (**a**) diffuse mesangial hypercellularity with segmental endocapillary hypercellularity and pink ribbon-like enhancement of glomerular basement membranes (periodic acid-Schiff stain, original magnification 600x); (**b**) C3 granular deposits diffusely in mesangial areas and segmentally along glomerular basement membranes (fluorescein-conjugated antihuman C3, original magnification 600x); (**c**) segmental electron dense transformation of glomerular basement membranes and mesangial areas (arrows, unstained grid, and original magnification 4000x); and (**d**) diffuse electron dense transformation of glomerular basement membranes (unstained grid, original magnification 12,000x)

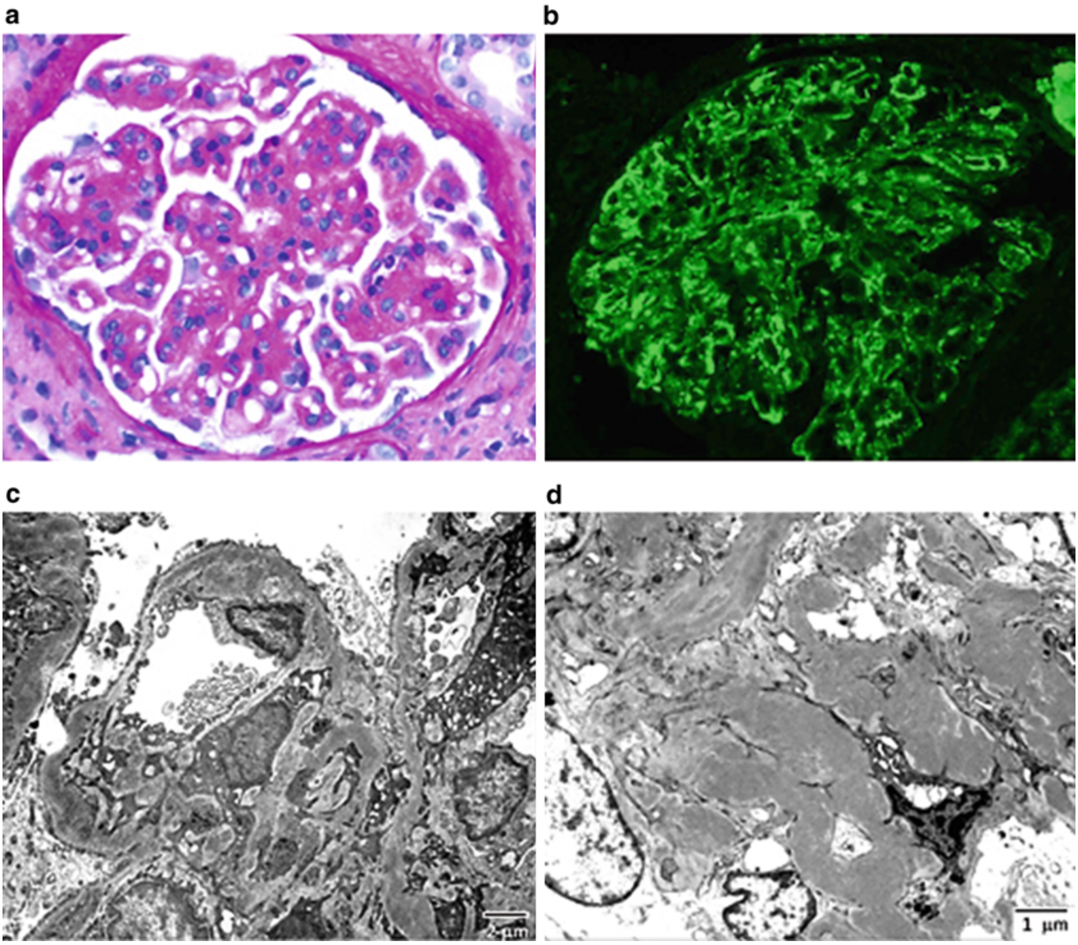

Fig. 2 C3 glomerulonephritis: (**a**) diffuse mesangial hypercellularity with endocapillary hypercellularity and thick glomerular basement membranes (periodic acid-Schiff stain, original magnification 600x); (**b**) C3 granular deposits diffusely in mesangial areas and along glomerular basement membranes (fluorescein-conjugated antihuman C3, original magnification 600x); (**c**) segmental charcoal gray transformation of glomerular basement membranes and mesangial areas (unstained grid, original magnification 4000x); and (**d**) diffuse charcoal gray transformation predominantly in mesangial areas but also within glomerular basement membranes (unstained grid, original magnification 8000x)

findings in C3G usually examining IgG, IgM, IgA, and C3c [18–22, 24–27]. C3 is intensely positive and dominant in both in the glomerular basement membranes and mesangial regions. In DDD, similar deposits may be seen along tubular basement membranes and the basement membrane of Bowman capsule. It is important to note that immunoglobulins and C1q are not uncommonly seen in C3G in a pattern similar to the C3 deposition [18–22, 24, 27].

Electron microscopy: DDD is characterized by the unique electron dense transformation of the basement membranes demonstrated using electron microscopy [10, 18–22, 28–30]. Though the diagnosis can be suspected by characteristic light and immunofluorescent features, the diagnosis must be confirmed by ultrastructural examination. The glomerular basement membranes undergo an extremely electron-dense transformation that looks as if the glomerular basement membranes had been calligraphed. In many areas, the entire length of the GBM will be replaced, while in other loops, only segments may be involved. Though the transformation usually involves the full thickness of the loop, it may include only a part. Subepithelial hump-like deposits with similar deep electron density are not uncommon [10, 18–22, 31]. In the deep mesangium, this same electron-dense transformation assumes a spheroid appearance.

In C3GN, the electron microscopic appearance of the deposits varies from an amorphous charcoal grey to well-defined and darker densities indistinguishable from immune-complex deposits [27, 32]. They are typically located in the subendothelial space and mesangium with occasional subepithelial deposits that may be hump-like.

Differentiating C3 Glomerulonephritis from Dense Deposit Disease

Dense deposit disease (DDD) is defined by the extremely electron dense transformation of the glomerular basement membranes as seen by electron microscopy, whereas C3GN is defined by the presence of C3 only or C3 dominance on immunofluorescence examination. C3GN is thus a diagnosis of exclusion since a C3-dominant pattern is significantly more common as a secondary event, particularly in infection-associated GN, rather than the extremely rare C3GN [33–35]. The use of pronase-digested paraffin immunofluorescence may reveal the presence of significant immunoglobulin deposition that would make C3GN less likely [36, 37].

Immunoglobulin-Associated Membranoproliferative GN

Immune complex-associated MPGN (IC-MPGN) is defined as a membranoproliferative light microscopy pattern with immunoglobulin dominance on immunofluorescence examination (Fig. 3). The overwhelming majority of cases are secondary (Table 1), and the presence of immunoglobulins and light chains is an important clue to the underlying condition. These should only be labeled “idiopathic” after an exhaustive clinical evaluation [15].

Membranoproliferative Glomerulonephritis Without Immunoreactants

This pattern is seen in the setting of chronic glomerular endothelial cell injury (Table 1). Residual acute changes my reveal the underlying cause. For example, segmental mesangiolysis and/or endothelial cell injury with fragmented red blood cells suggest chronic active thrombotic microangiopathy. Paraffin immunofluorescence is suggested if any electron-dense deposits are present on electron microscopy.

Transition Between IC-MPGN and C3G

Serial renal biopsies are rarely performed, and most patients are fitted into one of the above categories. However, there are multiple case reports of change over time from one form to another [38–43]. Typically, this is a change from an IC-MPGN to either C3GN or DDD (Fig. 4), though reports of infection-related glomerulonephritis (IRGN) evolving into C3G are also reported.

Lessons Learned from Animal Models

Genetically engineered and spontaneous animal models were instrumental in advancing our understanding of C3G pathogenesis. Spontaneous deposition of C3 within glomeruli has been reported in animals deficient in FH [44–47]. There was a pig strain that developed de novo FH deficiency [47] and a mouse strain (*Cfh*$^{-/-}$) generated by gene targeting in embryonic stem cells [44]. In both models, the deposition of C3 along the GBM was followed by electron-dense transformation of the GBM together with varying degrees of glomerular inflammation and structural damage (MPGN). In both models, terminal complement components were present in addition to C3, but IgG was absent in the initial lesions. Since these animals lacked FH, there was uncontrolled activation of C3 in the circulation, and consequently, levels of circulating

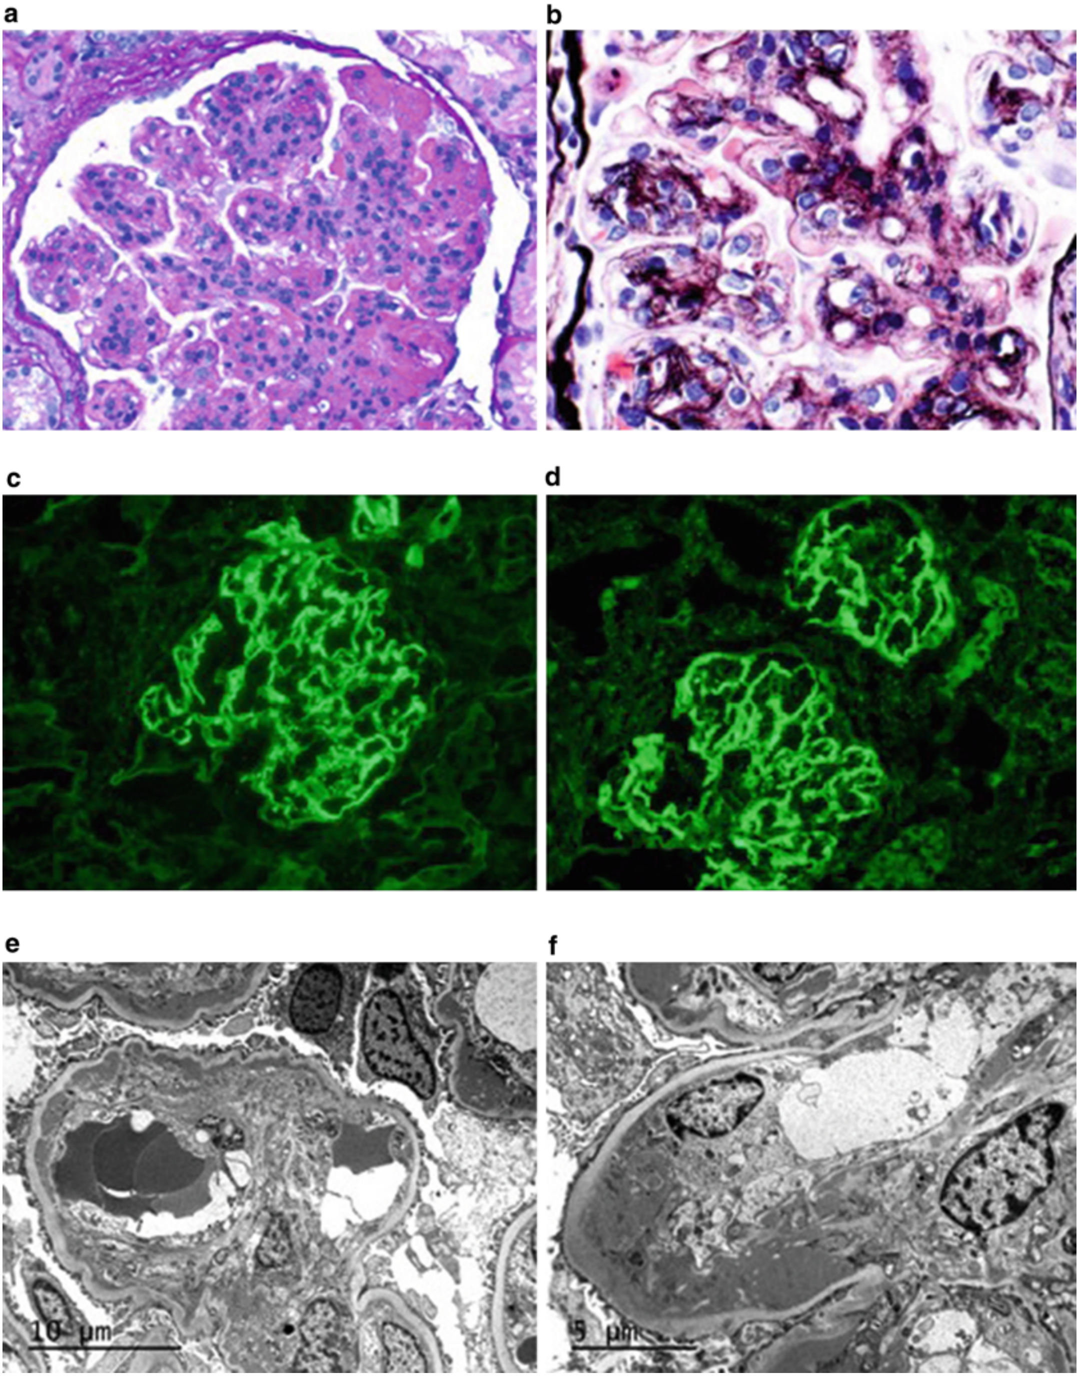

Fig. 3 Membranoproliferative glomerulonephritis, immune complex type: (**a**) mesangial and endocapillary hypercellularity with segmental lakes of pink deposits (periodic acid-Schiff stain, original magnification 600x); (**b**) glomerular basement membrane double contours with pink deposits. Mesangial and segmental endocapillary hypercellularity (Jones silver stain, original magnification 600x); (**c**) IgG granular deposits along glomerular basement membranes and in mesangial areas (fluorescein-conjugated antihuman IgG, original magnification 400x); (**d**) C3 granular deposits similar to IgG (fluorescein-conjugated antihuman C3, original magnification 400x);

C3 were extremely low. The *Cfh*$^{-/-}$ strain has been studied in detail and has provided some important insights into the pathogenesis of C3G. It is important to note here, however, that this is a model of C3G associated with complete FH deficiency. This is an extremely rare cause of C3G. So, care is needed in linking the findings from the *Cfh*$^{-/-}$ strain to human C3G.

The most obvious lesson from the *Cfh*$^{-/-}$ strain is the critical importance of FH in protecting the GBM from spontaneous C3 deposition. It is remarkable that simply removing this regulator results in florid C3 deposition along the GBM together with terminal pathway components. When C5 activation was prevented, by intercrossing the *Cfh*$^{-/-}$ strain with C5-deficient mice, the abnormal glomerular C3 remained unchanged but the severity of both spontaneous and experimental glomerulonephritis was reduced [48]. This indicated that strategies to block C5 activation might have utility in reducing glomerular inflammation in C3G but would not alter glomerular pathology driven by the abnormal C3 deposition.

In contrast to blocking C5, restoring C3 regulation in the *Cfh*$^{-/-}$ strain would be expected to ameliorate C3G. The first attempts to do this were by adding back FH. Administration of either mouse or human FH to *Cfh*$^{-/-}$ mice reduced glomerular C3 staining and increased circulating C3 levels [49–51]. Constructs that contain only the regulatory and targeting domains of FH, termed mini-FH molecules, also ameliorated glomerular C3 [52]. Other approaches were the administration of novel regulatory proteins that target to sites of complement activation. These included TT30 [53], a protein containing the complement regulatory domains of FH (FH_{1-5}) linked to the complement-binding domains of complement receptor 2; and homodimeric FH molecules [54], mini-FH molecules that contain complement-binding domains of factor H-related protein 1 (FHR1).

Another approach to prevent uncontrolled C3 activation was to block AP activation in the *Cfh*$^{-/-}$ mice by removing the activation proteins of the AP, i.e., FB or FD, or by removing properdin, the AP positive regulator. The *Cfh*$^{-/-}$ mice did not develop spontaneous C3G in the absence of FB, an essential activation protein of the AP [44]. In the absence of FD, the *Cfh*$^{-/-}$ mice did not develop C3 along the GBM but over time did develop mesangial C3 deposits and glomerular injury, suggesting that there was residual AP activity in the *Cfh*$^{-/-}$ mouse sera despite deficiency of FD [55]. Properdin deficiency in the *Cfh*$^{-/-}$ strain resulted in worsening of glomerular C3 deposition [56, 57]. This was unexpected since removal of this positive regulator of the AP C3 convertase would be expected to slow C3 activation. What are the messages from these studies for the treatment of C3G? Taken together, these data indicate that inhibiting FB or FD can modulate AP-driven glomerular C3 deposition, but inhibition of properdin could make it worse.

A further insight was derived from studying the effects of FI, the enzyme that cleaves C3b to iC3b and then to C3c and C3dg. In the *Cfh*$^{-/-}$ strain, the uncontrolled C3 activation results in C3b which is cleaved by FI to iC3b and C3dg. However, in *Cfh*$^{-/-}$ mice that are also deficient in FI, activated C3 remains as C3b only. Interestingly, while abnormal glomerular C3 developed in both strains, the C3 in the mice with combined deficiency of FH and FI was mesangial in location, while in the *Cfh*$^{-/-}$ strain the C3 was located along the GBM. These data indicated that during uncontrolled C3 activation the nature of the activated C3 fragment could influence where it accumulates in glomeruli [58].

The nature of the activated C3 is also relevant to its longevity in glomeruli. When FH was

Membranoproliferative glomerulonephritis, immune complex type (**a**–**d**): (**a**) mesangial and endocapillary hypercellularity (periodic acid-Schiff stain, original magnification 400x); (**b**) IgG deposits along glomerular basement membranes and in mesangial areas (fluorescein-conjugated antihuman IgG, original magnification 200x); (**c**) mesangial and endocapillary hypercellularity with immune complex type subendothelial and mesangial deposits (unstained grid, original magnification 4000x); (**d**) immune complex type subendothelial deposits with endocapillary hypercellularity (unstained grid, original magnification 12,000x). Second biopsy 23 weeks later. C3 glomerulonephritis (**e**–**g**); (**e**) diffuse mesangial hypercellularity with segmental, mild, endocapillary hypercellularity. No glomerular basement membrane double contours (periodic acid-Schiff stain, original magnification 600x); (**f**) C3 granular deposits diffusely in mesangial areas and segmentally along glomerular basement membranes (fluorescein-conjugated antihuman C3, original magnification 400x); (**g**) segmental charcoal gray transformation of glomerular basement membranes and mesangial areas (unstained grid, original magnification 8000x); and (**h**) diffuse charcoal gray transformation predominantly in mesangial areas but also within glomerular basement membranes (unstained grid, original magnification 12,000x)

administered to *Cfh*$^{-/-}$ mice there was a striking reduction in glomerular C3b/iC3b/C3c which was evident at 24 h. However, glomerular C3dg persisted for weeks. Similarly, in models of immune complex experimental nephritis, glomerular C3c was cleared by 85% in 24 h after cessation of complement activation, whereas glomerular C3dg persisted for weeks [59]. This is most likely because C3dg is covalently attached to surface structures within the GBM or mesangial matrix. Importantly, it tells us that the type of C3 fragment detected in the renal biopsy matters if the aim is to determine if complement activation has ceased (C3dg alone) or is ongoing (C3c and C3dg). This has clear implications for clinical trials of complement inhibitors that use renal biopsy deposition of C3 as markers of efficacy.

Mutations in FH are associated with susceptibility to atypical hemolytic uremic syndrome (aHUS) (see chapter on aHUS) indicating that defects in the complement AP can give rise to at least two distinct renal pathologies: thrombotic microangiopathy (TMA) (i.e., aHUS) and glomerulonephritis (i.e., C3G). This is explained by the observation that the majority of aHUS-associated CFH mutations do not result in complete deficiency of FH but selectively impair the surface C3b recognition domains of the protein. Mice expressing a mutant FH molecule that functionally mimicked the human aHUS-associated mutations developed TMA not C3G [48], and this was dependent on C5 [60]. These studies indicated that for aHUS to develop there need to be both defective complement regulation along the renal endothelium ("the fire") and sufficient C3 and C5 ("the fuel") to mediate the damage. In *Cfh*$^{-/-}$ mice, the absence of FH means that the FH-mediated regulation of complement along endothelium is not possible. However, these mice have very low circulating C3 and C5 levels so lack sufficient complement to cause damage and are therefore protected against aHUS. This indicates that the balance between surface regulation (preventing complement-mediated damage to surfaces like the renal endothelium) and plasma regulation (preventing depletion of C3 and C5) critically influences the nature of the glomerular pathology.

We lack models of C3G associated with C3 nephritic factors (C3NeFs). But there are two old, but important, studies of relevance. In both, the aim was to generate chronic C3 activation in an attempt to mimic the actions of C3NeF and to determine if this resulted in glomerular C3 deposition. Despite achieving prolonged periods of hypocomplementemia using either zymosan in rabbits [61] or cobra venom factor in mice [62], neither strategy resulted in glomerular C3 deposition. More recently, mice expressing human C3 have been shown to develop spontaneous C3G analogous to that seen in the *Cfh*$^{-/-}$ mice [63]. The pathology improved with anti-C5, anti-FB, and anti-C3b treatment. However, the reason for the uncontrolled C3 activation in this humanized strain was because *human* C3 cannot be regulated by *mouse* FH and *mouse* FI. So, the pathology in this model was a consequence of "de facto" FH deficiency, a consequence of interspecies differences in complement regulators. Taken together with the large data sets derived from the FH-deficient animal models, perhaps this is telling us that FH is the critical regulator of glomerular C3 homeostasis, i.e., when there is uncontrolled C3 activation but normal FH function, glomerular C3 deposition does not occur. It also raises questions about the relevance of C3NeF to pathogenesis of C3G.

We lack models of FHR-associated C3G where circulating complement is typically normal and where there appears to be local glomerular activation of complement. In these pathologies, the hypothesis is that the abnormal FHR proteins interfere with the ability of FH to regulate glomerular C3 activation [64, 65].

Lessons Learned from Patients

Complement dysregulation in C3G patients may occur via one or more of the following scenarios:

- Antibodies stabilizing the AP C3 convertase, thus prolonging the natural decay of the AP C3 convertase, rendering it overactive
- Mutations or antibodies to FH or FHR that result in the absence or loss of function of FH resulting in loss of control of the AP C3 convertase and its enhanced activity
- Mutations in C3 or FB that result in an exceedingly stable C3 convertase with prolonged decay and enhanced function

In all scenarios, the functional consequence is an enhanced activation rate of C3. Some antibodies prolong the half-life of the CP C3 convertase, or the (AP or CP) C5 convertase [66, 67]. Of note, some C3NeFs (properdin dependent) also stabilize the C5 convertase, hence called C5NeF, and result in terminal pathway activation and elevated sC5b-9 levels [68, 69].

The pathogenetic role of complement is further supported by the detection of complement alternative and terminal pathway proteins in the glomerulus of patients with C3G [16, 17].

Autoimmune Forms of C3G

In 1965, the first association of decreased serum C3 levels and MPGN was reported, followed by the hypothesis of a circulating factor in GN patients leading to increased C3 cleavage [70]. Subsequently, an antibody binding to a neoepitope of the complement AP C3 convertase (C3bBb), enhancing its stability and function (i.e., C3 activation), was detected and named C3NeF [66, 71]. Additional autoantibodies or nephritic factors were detected that prolonged the half-life of the complement AP or CP C3 or C5 convertases (Table 2). C3NeF and other autoantibodies found in MPGN were also detected in other renal diseases, such as systemic lupus

erythematosus (SLE) [72–74], IRGN [75], meningococcal meningitis [76], and in healthy individuals, rendering the interpretation of their pathogenic value controversial [66, 77].

C3NeF is the most prevalent antibody and was detected in 86% of DDD, 46% of C3GN, and up to 50% of patients with IC-MPGN, respectively, and is associated with decreased C3 levels [68, 78]. C3NeF levels might fluctuate during the clinical course and do not necessarily reflect disease activity or treatment status [79]. As C3NeFs are heterogeneous, reliable detection is challenging, and currently no international standard for C3NeF detection exists [66]. The finding of C3NeF does not exclude the coexistence of complement mutations, and despite C3NeF positivity, comprehensive complement diagnostics should be performed (Table 4) [80].

Anti-C3b and Bb antibodies, both stabilizing the AP C3 convertase, have been reported in several patients with C3G and IC-MPGN [81, 82]. Fifty percent of those patients had a history of infection [81]. Patients with both anti-C3b and Bb antibodies presented with terminal pathway activation, and worse renal outcome was reported [81, 83]. FH autoantibodies, frequently associated with aHUS [84], were reported but are rare in MPGN and in contrast to aHUS seem to affect FH cofactor activity [85–87].

C4NeF has been mainly detected in IC-MPGN and C3G patients with a prevalence of 3–20% in different cohorts. C4NeF commonly coexists with C3NeF, and a favorable long-term outcome was reported [88–90]. C5NeF describes antibodies, stabilizing the C3 and C5 complement AP convertases, and has been detected in patients with C3G and DDD [91]. It is unclear whether this is a unique nephritic factor or represents a C3NeF with terminal pathway dysregulation [66].

Genetic Forms of C3 Glomerulopathy

Genetic studies have showed that approximately 25% of patients with C3G have rare or unique variants in complement genes [68, 92, 93]. Genetic causes are more common in C3G, than DDD, and are less likely found in IC-MPGN patients [68, 92]. In a large cohort of idiopathic/primary IC-MPGN, Iatropoulos et al. recently showed that the frequency of genetic variants in complement AP genes or C3NeF, or both, was similar to the frequency in patients with C3G [78, 94]. This study also distinguished clusters of patients based on inflammatory markers on biopsy and biochemical findings irrespective of a C3G or IC-MPGN diagnosis. Results of this study highlight shared mechanisms across the individual diagnoses within the MPGN/C3G spectrum [94]. Detailed understanding of the specific complement dysregulation seems more important than the differentiation between C3G and IC-MPGN with respect to complement-targeting therapies (Table 5).

To date, mutations have been reported in the following complement genes: *CFH*, *CFHR5*, *CFI*, *MCP*, *C3,* and *CFB* [64, 68, 95–108]. Additional mutations or internal duplications in genes encoding FH-related proteins (*CFHR*), or formation of hybrid genes, were associated with familial C3G [109, 110]. Risk haplotypes were identified in *CFH*, *C3,* and *MCP*/*CD46*, with *CFH* Y402H haplotype more frequently reported in DDD, and *MCP*-652A4G polymorphism in C3G [68, 95]. The presence of two or more complement haplotypes increased the risk of disease [68, 95].

Table 3 gives an overview of pathogenic or likely pathogenic variants, rare variants, and polymorphisms associated with C3G. Interestingly, several variants have already been described in patients with aHUS [68]. Compared to aHUS, *CFH* mutations associated with C3G are preferentially located in the N-terminal region of FH or affect Cys residues throughout the FH protein. In either case, these mutations result in the loss of function of FH

Table 3 Autoantibodies (Ab) associated with membranoproliferative glomerulonephritis (MPGN)

Antibodies	Incidence	Coexisting with C3Nef	Effect on complement	Routine testing
C3NeF [68, 77]	Common	–	Stabilizes AP C3 convertase	Yes[a]
C4NeF [88–90]	Rare	Yes	Stabilizes CP C3 and C5 convertases	No
C5NeF [66, 91]	Rare	Yes	Stabilizes AP C5 convertase	No
Anti-Factor B Ab [82, 83]	Rare	No	Stabilizes AP C3 convertase	No
Anti-C3b Ab [83]	Rare	No	Stabilizes AP C3 convertase	No
Anti-Factor H Ab [87]	Rare	Yes	Fluid phase regulation	Yes

[a] Some functional tests are only done in specialized labs

AP alternative pathway, *CP* classic pathway, *NeF* nephritic factor complement regulatory activity similar to *CFH* null genotype [68, 104, 111]. Deletions of *CFHR3-CFHR1*, unlike in (DEAP-) DEAP-HUS patients, have not been associated with FH autoantibodies in patients with C3GN [83]. Most *CFI* variants associated with MPGN were already reported in patients with aHUS, and the functional consequences in fluid phase are not clear [68].

In 2009, Gale et al. described in 26 of 84 people of Cypriotic ancestry with unexplained renal disease a variation in *CFHR5* comprising duplication in its dimerization domain [99]. Several more mutations and hybrid variants in *CFHR* genes have been detected and are associated with C3G. The role of FHR in C3G was unclear until de Jorge et al. reported that FHR1, FHR2, and FHR5 might form homo- and heterodimers among themselves and with FH [64]. In the dimer form, these proteins are able to compete with FH for C3b binding and protect C3b from inactivation and the complement AP C3 convertase from its decay. This process, termed “deregulation,” was increased in patients with *CFHR* hybrids or *CFHR5* mutations (Table 3) [64, 99, 110].

In 2013, Ozaltin et al. published several patients with MPGN with a homozygous mutation in *DGKE*, an intracellular lipid kinase that modulates phosphoinositol signaling in the plasma membrane [112]. *DGKE* mutations might also be associated with thrombotic microangiopathy [113, 114]. Bu et al. found heterozygous variants in *DGKE* in several patients with C3G, where the clinical impact is still unclear [93].

Of note, a recent study from the UK on 146 patients of European ancestry with primary MPGN did not find a significant enrichment of variants in (candidate) complement AP genes, or in genes associated with aHUS, but rather detected a significant variant in an HLA locus [115].

Clinical Features

MGPN, C3GN, and DDD are rare diseases with an individual annual incidence estimated at 1–2 per million per total population (both pediatric and adult) [116, 117]. Once thought to be primarily pediatric diseases, it is clear that they also commonly present in the adult population [68]. The recent French series noted that 39% of patients were less than 16 years at diagnosis; the mean age at diagnosis for MPGN, DDD, and C3GN was 20.7 ± 16.8 years, 18.9 ± 17.7 years, and 30.3 ± 19.3 years, respectively [68]. Estimates range from 43% to 58% of patients with DDD, and 25–54% of patients with C3GN were below 16 years at diagnosis. Within the pediatric population, DDD tends to present at a younger age, with 70% of patients diagnosed prior to 15 years [118]. There is a slight bias with males predominating in MPGN, DDD, and C3GN [68, 116]. As the large case series that discriminate MPGN, DDD, and C3GN are predominately from Northern European populations, it is not clear if there are ethnic or racial differences in disease frequency.

The clinical presentations of MPGN, DDD, and C3GN are nonspecific and show significant overlap with regard to clinical features. Depending on the case series, nephrotic syndrome has been reported as the presenting feature in 40–65% of patients with MPGN, 30–40% with DDD, and 25–40% with C3GN. Regardless of disease type, microscopic hematuria is reported in 40–75% of patients, gross hematuria in 10–20%, and non-nephrotic proteinuria in 30–40%. Presentations with acute glomerulonephritis are common in MPGN, DDD, and C3GN, with hypertension noted in 30–60%, and renal insufficiency in 20–50% patients [21, 32, 68, 116], while rare, rapidly progressive glomerulonephritis has been reported in MPGN, DDD, and C3GN.

As the classification system for MPGN has recently evolved, our understanding of the differences in the clinical presentations of MPGN versus C3GN is limited, by sparse published literature. Doubtless, there will be refinements regarding variations in presentation; however, it is unlikely that there will be unique features that clearly distinguish MPGN, DDD, and C3GN clinically. The exception to this appears to be *CFHR5*-associated C3GN which presents in childhood with persistent microscopic hematuria, synpharyngitic gross hematuria, and a strong family history of ESKD. At present, this form of G3GN has been reported primarily in the Cypriot population, but also in two patients with non-Cypriot heritage [99, 119–121].

Hypocomplementemia has usually been regarded as a distinguishing feature of MPGN I (low C3 and low C4) and other types of MPGN (low C3 and normal C4) [122]. In the current classification, MPGN is regarded as a form of immune complex disease, and depressed C4 levels are commonly held as a distinguishing feature; C3GN is thought primarily to be due to dysregulation of the complement AP, and therefore, C4 levels are usually normal. Recent retrospective case series comparing complement levels in patients with MGPN, DDD, and C3GN generally confirm the utility of C3 and C4 levels in distinguishing these disease types [68, 116]. There were, however, important caveats in these studies. In the French series (115 patients), at diagnosis, only 46% of MPGN patients had C3 levels of less than 66 mg/dl, and only 2.4% had C4 levels less than 9.3 mg/dl; low C3 levels were noted in 59% of DDD patients and 39.6% of C3GN patients. One patient with DDD and none with C3GN showed low C4 levels [68]. The series from England (80 patients) reported low C3 levels (<65 mg/dl) in 79% of DDD and 48% of C3GN patients, with suppressed C4 levels (<16 mg/dl) in 15% of DDD and 36% of C3GN patients [116]. Based on these and other reports, it appears that while assessment of C3 and C4 levels is suggestive of a diagnosis of MPGN, DDD, or C3GN, suppressed C3 or C4 levels are neither sufficient nor essential in the presentation of MPGN, DDD, or C3GN [68, 116]. It is important to recognize that of the combined patients reported in these case series with biopsy-proven MPGN, DDD, or C3GN, 43% had normal C3 levels at the time of diagnosis [68, 116]. Patients with *CFHR5*-associated C3GN are also reported to have normal serum C3 concentrations [123].

Extrarenal manifestations are uncommon in C3G. These include acquired partial lipodystrophy (aPL) and ocular C3 deposits, similar to soft drusen seen in age-related macular degeneration (AMD) [101]. Interestingly, polymorphisms in complement genes are also associated with the risk of developing AMD [124]. These drusen consist of C3 split products and FH [125, 126]. The long-term risk for visual problems is about 10% [127]. aPL usually precedes the diagnosis of MPGN and may present with low C3 levels and C3NeF. It is presumably caused by complement dysregulation on adipocytes [128, 129].

Diagnosis

The clinical presentations of MPGN, DDD, and C3GN are extremely variable and overlap with many other glomerular diseases, ranging from subtle/subclinical to acute and severe, as exemplified in the following scenarios:

- An accidental finding on routine urinalysis of non-nephrotic proteinuria, usually accompanied by microscopic hematuria.
- Macrohematuria concomitant or 2–3 weeks after an intercurrent infectious episode, most frequently of the upper respiratory tract.
- Nephrotic range proteinuria, with or without clinical signs of nephrotic syndrome and renal function impairment.
- Very rarely, nephrotic-range proteinuria in the setting of thrombotic microangiopathy.

Measuring circulating C3 and C4 is helpful; typically, these forms are characterized by low-circulating C3 with normal C4, especially in children. However, this is not always the case [68].

Diagnosis relies necessarily on a renal biopsy. For C3G, while the light microscopy picture will be that of proliferative GN of varying degrees of intensity, the diagnostic feature is intense and dominant C3 staining. As detailed above, electron microscopy allows distinction between DDD and C3GN based on the nature and location of the deposits.

IC-MPGN, characterized by intense and dominant or codominant immunoglobulin deposition, does not exclude a complement AP-driven pathogenesis [78, 94]. As described above, in some cases, a renal biopsy performed at onset can show both IgG and C3, while a subsequent renal biopsy performed in the same patient may reveal a clear C3-dominant pattern, as seen in classic C3G

(Fig. 4). When a proliferative GN due to impaired control of the complement AP is suspected based on the renal biopsy findings and clinical features, a full workup of complement diagnostics should be performed (Table 4).

Differential Diagnosis

In the pediatric population, low C3 and/or C4 levels are seen primarily in patients with either SLE, other forms of IC-MPGN, or C3G. A thorough history and physical examination with attention to extrarenal disease manifestations such as arthralgias, rash, neurologic, hepatic, lung, or cardiac involvement combined with ANA and anti-dsDNA antibody titers, laboratory evidence of hemolysis, leukopenia, coagulopathy, myositis, or hepatitis, strongly support a diagnosis of SLE as opposed to C3G. Although exceedingly rare in the pediatric population, essential cryoglobulinemia may also present with multiorgan involvement and systemic findings. Of note, IC-MPGN may present with low C3 *and* C4 levels (Table 1) [130]. Diseases presenting with low C3 and normal C4 levels are mainly IRGN, other forms of IC-MPGN and C3G. Very rarely, isolated low C3 and proliferative nephritis can be due to chronic bacteremia or shunt nephritis. The presence of persistent fevers or VA-shunts should alert the physician to the possibility of these clinical entities.

Distinguishing IRGN and C3G at disease onset can be challenging, as the clinical picture, serological finding, and renal biopsy picture are very similar. A renal biopsy is rarely required in a child with a classic course of poststreptococcal GN. If performed, LM shows an acute proliferative and exudative GN, IF most often both C3 and IgG and and EM subepithelial hump like deposits. However, in other forms of IRGN, such a pattern is actually rare and can be easily misdiagnosed as C3G, because, as discussed above, neither codominant IgG and C3 nor subepithelial humps rule out C3G. Recent evidence shows that transient anti-FB antibodies are frequently observed in children with acute IRGN, while they are very infrequent in C3G [131]. This laboratory exam, however, is available only in centers with a high degree of expertise in complement diagnostics. Ultimately, it is the clinical evolution that reveals whether the patient has an acute, self-limiting condition such as IRGN or a chronic, relapsing/remitting disease such as C3G. DDD or C3GN should be considered if the C3 level does not return to normal within 8–12 weeks of

Table 4 Diagnostic workup for IC-MPGN/C3G (modified from Vivarelli M, Thurman J; NKF Primer on Glomerular diseases)

History	Family history of hematuria, glomerulonephritis, and kidney failure
	Gross hematuria (if yes, concomitant or 2–3 weeks subsequent to infection; number of episodes)
	Infection (especially upper respiratory tract) in the preceding 2–3 weeks
	Previous urinalysis results?
Clinical examination	Signs of nephrotic syndrome (peripheral and periorbital edema, weight increase)
	Blood pressure
	Presence of frothy urine, reduction in urine output
	Extrarenal features: partial lipodystrophy, retinal drusen
Laboratory workup	Urinalysis, 24-hour proteinuria, microhematuria
	Complete blood count, urea, creatinine, protein, IgG, IgA, and IgM
	Serum C3, C4
	Antinuclear antibody, antidouble stranded DNA antibody; serology for hepatitis C and B virus; and serum protein electrophoresis
Complement workup	C3 nephritic factor (C3Nef), C4Nef, and C5Nef
	Anti-FH antibodies, anti-FB antibodies, and anti-C3b antibodies
	Soluble C5b9, FH, FI, Bb, properdin, and total hemolytic complement (CH50)
	Genetic screening (next-generation sequencing plus multiplex ligation-dependent probe amplification): *C3, CFH, CFI, CFB, MCP, CFHR1-5, THBD*

presentation or in the presence of active nephritis (relapsing macrohematuria and/or proteinuria) more than 8–12 weeks from the initial episode [75]. Elevated ASO titers, classically associated with IRGN, can be found also in C3G. A report by Medjeral-Thomas et al. noted elevated ASO titers in 43% of patients with DDD and 57% of patients with C3GN [116]. Finally, the presence of normal complement levels does not rule out C3G as it uncommonly presents in this fashion.

Therapy

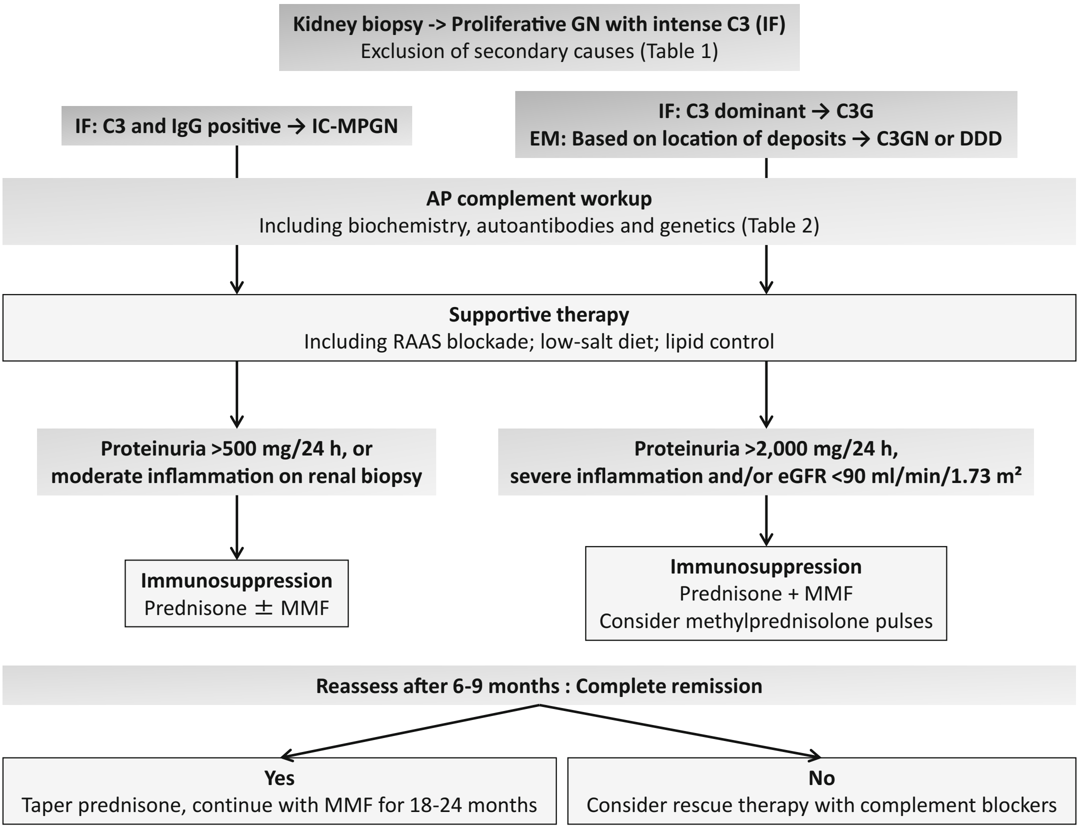
No evidence-based standard treatment for patients with IC-MPGN or C3G exists, and current treatment recommendations are based on small studies and expert opinion [132]. Figure 5 proposes a management algorithm.

Supportive Therapy

All patients with IC-MPGN or C3G should receive renin-angiotensin-aldosterone system (RAAS) inhibition with angiotensin-converting-enzyme inhibitors (ACEi) or angiotensin II receptor antagonists (ARB) due to their antiproteinuric and antihypertensive effect. The use of ACEi or ARB was associated with better renal survival in C3G patients [68]. Low-salt diet and, when necessary and possible (in older children), lipid control must also be implemented.

Immunosuppressive Therapy

In children, there are multiple studies on the use of steroids in MPGN. A beneficial effect of steroids for proteinuria and long-term renal function was



Kidney biopsy -> Proliferative GN with intense C3 (IF)
Exclusion of secondary causes (Table 1)
IF: C3 and IgG positive → IC-MPGN
IF: C3 dominant → C3G
EM: Based on location of deposits → C3GN or DDD
AP complement workup
Including biochemistry, autoantibodies and genetics (Table 2)
Supportive therapy
Including RAAS blockade; low-salt diet; lipid control
Proteinuria >500 mg/24 h, or
moderate inflammation on renal biopsy
Proteinuria >2,000 mg/24 h,
severe inflammation and/or eGFR <90 ml/min/1.73 m²
Immunosuppression
Prednisone ± MMF
Immunosuppression
Prednisone + MMF
Consider methylprednisolone pulses
Reassess after 6-9 months : Complete remission
Yes
Taper prednisone, continue with MMF for 18-24 months
No
Consider rescue therapy with complement blockers

Fig. 5 Therapeutic algorithm for IC-MPGN and C3G. For further details, please refer to paragraph on *Therapy*

detected by using long-term low-dose prednisone. However, only a subgroup of patients with MPGN type I will respond, and it may only be a partial response. Prednisone is given at a dose of 60 mg/m^2 (maximal 60 mg/d) for 4 weeks (induction), followed by 40 mg/m^2 on alternate days for another 4 weeks, and then tapered for a total of 6–12 months (maintenance). This is beneficial also in patients with C3G. It is advisable to use oral prednisone if proteinuria is >500 mg/24 h, or if the renal biopsy shows a moderate degree of inflammation. In the presence of proteinuria, >2000 mg/24 h or if the renal biopsy shows intense inflammation with endo- or extracapillary proliferation or if renal function is impaired, pulses of intravenous methylprednisolone (1000 mg/1.73 m^2 repeated 3 times), followed by oral prednisone, should be considered.

Mycophenolate mofetil (MMF) has been administered alone or in combination with prednisone in idiopathic MPGN and generated encouraging results. In 13 patients with steroid-resistant primary MPGN, the addition of MMF resulted in sustained improvement (1 year follow-up) of proteinuria and renal function [133]. In 51 patients with primary GN, including 15 patients with MPGN, partial or complete remission was reported in 70% after 1 year [134]. In a small case series of nine children with MPGN I, treatment with MMF and prednisone for a mean time of 40 months resulted in complete or partial response in five. All patients with low C3 levels were treatment failures [135]. In C3G, Caravaco-Fontan et al. recently described 97 patients (81 with C3GN, 16 with DDD), of whom 42 received corticosteroids plus MMF. This subgroup showed a higher rate of remission (79%) and a lower likelihood of renal failure (14%) compared to patients receiving other immunosuppressants, eculizumab, or conservative treatment. The superiority of this therapeutic approach was seen both in patients with genetic complement abnormalities and in those with autoantibodies to complement components [136]. The Columbia group had previously described 30 young adults with C3G treated with MMF plus corticosteroids with a median follow-up of 22 months. Twenty-two patients (67%) were defined as responders, having achieved partial or complete remission. For those who tapered MMF, relapse rate was 50% [137]. In both of these studies, heavier baseline proteinuria was a negative predictor of response.

In our experience, as is advised by the KDIGO expert opinion, MMF is beneficial in patients both with IC-MPGN and with C3G with intense proteinuria [132]. Following a prednisone taper and discontinuation over 6–9 months usually MMF monotherapy is continued for a total of 18–24 months.

Calcineurin inhibitors (cyclosporine A and tacrolimus) have been used in steroid-resistant MPGN patients. One study demonstrated its efficacy in a trial on 18 patients with refractory MPGN and low-dose prednisone therapy, by inducing long-term (2 years) reduction of proteinuria and stable renal function in 94%. Only one patient showed a recurrence after treatment discontinuation [138]. In 11 adult patients with steroid resistant, including 5 with cyclophosphamide-resistant MPGN, tacrolimus plus prednisone in 6 resulted in partial/complete remission in 9 [139, 140]. In a study on 60 patients with C3G, cyclophosphamide appeared beneficial in the subset of adolescent and adult patients [141]. In two children with MPGN and suboptimal response to prednisone, a rapid and complete remission was achieved with tacrolimus [142]. In two patients with DDD, low-dose prednisone and cyclosporine A were able to induce remission [143, 144]. On the other hand, Appel et al. did not show benefit of calcineurin inhibitors in the therapy of DDD [127]. In our experience, calcineurin inhibitors can aid in achieving remission in patients with both IC-MPGN and C3G who maintain significant proteinuria despite 6–9 months of immunosuppressive treatment.

The detection of C3NeF has prompted the use of B-cell-depleting agents like rituximab. Several case reports in patients with MPGN I, especially with IC-mediated disease, indicate partial or complete remission after administration of rituximab (in half of the cases in addition to steroids), in 11 of 13 patients [145–149]. Despite a decrease in C3NeF levels, two patients with DDD did not show any change in proteinuria or renal function [150, 151]. Of note, both patients were rescued by eculizumab therapy (below). Most authors describing treatment of C3G find no benefit in the use of rituximab, even in C3Nef positive patients. It is unclear whether this lack of response indicates that C3Nefs are not drivers of disease, or whether to be clinically effective their levels need to be brought to zero and not merely reduced.

Complement Targeting Therapy

The growing body of evidence on the role of complement AP dysregulation, in IC-MPGN and in C3G, clearly indicates that complement inhibition may be a targeted and therefore effective therapeutic strategy for these glomerular diseases. Several case reports exist on the use of plasma exchange in patients with MPGN I and DDD for disease features and recurrence in native and graft kidneys. Partial or complete remission was reported in 17 of 21 patients (81%) reported in the literature [147, 152–163]. In one patient with IC-MPGN (MPGN I) despite a transient improvement of renal function and proteinuria in response to prednisone, MMF, and plasma exchange, her condition worsened including seizures, respiratory distress, and sustained anuria. Due to deletion of *CFHR1* (without FH autoantibodies), low C3 and elevated sC5b-9, indicating complement AP and terminal pathway activation, and TMA-related symptoms, the patient was switched from plasma exchange to eculizumab. This was associated with improved clinical condition, proteinuria, and renal function [154]. One report shows the successful therapy of MPGN recurrence during pregnancy and delivery of a healthy child [164].

Three case reports, including two siblings with DDD on the background of *CFH* mutation in SCR4, and one patient with MPGN I and *MCP/CD46* mutation were treated for >3 years with chronic infusion of fresh frozen plasma (FFP). FFP as maintenance therapy, individualized per patient needs, prevented progression and maintained kidney function [100, 104, 154]. However, plasma infusions might not be enough as induction therapy [165].

Regarding complement inhibitors, the only currently available agent on the market is a terminal pathway inhibitor, the anti-C5 monoclonal antibody eculizumab and its new long-acting form, ravulizumab. In 2012, several reports of the successful use of eculizumab in patients with MPGN were published [154, 166–168]. Eculizumab is a monoclonal antibody-binding C5 and therefore preventing the assembly of the terminal complement complex (TCC, C5b-9) [169]. This complex is integrated in cell membranes and can lead to cell lysis. Its role in the pathogenesis in C3G is not known; however, elevated soluble C5b-9 levels were detected in some patients with C3G, and in animal models C5 knock-out ameliorated the disease [170].

At present, a number of small case series and single case reports have shown mixed results. Six are part of a small clinical trial while the others are single case reports [150, 154, 166–168, 171–173]. A significant response was reported in ten, a partial response in one, and no response in two of these patients, as reviewed by Vivarelli et al. [174]. These patients include cases of C3G and DDD, in native and transplanted kidney and both cases with C3NeF and genetic mutations. Taken altogether, a better outcome seemed to be associated with elevated sC5b-9 levels and shorter disease duration [174]. More recently, a retrospective French study evaluated 26 patients, 13 of whom were children, with a median treatment duration of 14 months [175]. In this study, 6 patients (23%) had a global clinical response, 6 (23%) had a partial clinical response, and 14 (54%) had no response. The patients with a global clinical response had rapidly progressive disease and more intense glomerular extracapillary proliferation, while age, extent of tubulointerstitial fibrosis, frequency of nephrotic syndrome, and frequency of alternative pathway genetic or antibody-mediated activation did not differ across the groups. These results suggest that eculizumab may target glomerular inflammation without affecting the AP complement dysregulation that is the main driver of the disease. Two patients with a mixed aHUS/C3G phenotype benefiting from treatment for eculizumab have been recently described, suggesting that eculizumab is most likely to benefit patients with an endothelial AP complement dysregulation (Busutti et al. KI Reports in print).

However, the only formal clinical use of eculizumab in IC-MPGN and C3G gave very disappointing results. The EAGLE study [176] evaluated ten patients (six with MPGN, four with C3G), all with normal renal function, intense (>3500 mg/24 h) proteinuria, and highly elevated sC5b9 (>1000 ng/ml), and receiving eculizumab for two sequential 48-week periods separated by one 12-week washout period. Primary outcome was change in 24-hour proteinuria (median of three consecutive measurements) at 24 and 48 weeks. While terminal complement pathway activation was successfully blunted in all patients, only three patients achieved partial remission of proteinuria. During the first treatment period, proteinuria, and blood levels of albumin and lipids, improved, but these benefits were lost during the washout period and never regained in seven patients.

Taken altogether, based on the information currently available, it appears reasonable to attempt eculizumab in patients with C3G/IC-MPGN only as a rescue therapy when immunosuppression has failed. Patients with intense inflammation, elevated sC5b9, recent disease onset, and/or mixed aHUS/C3G clinical presentation are more likely to respond.

A number of other complement inhibitors are being investigated in adults and adolescents with IC-MPGN and C3G. Some of these agents block the complement pathway further upstream, at the level of AP C3 convertase. In theory, these agents will be more effective than terminal pathway inhibitors, at least in a subset of patients. While results of these trials are preliminary, hopefully, more targeted therapies will be available soon (Table 5). However, nonspecific immunosuppression is effective in the majority of children with IC-MPGN or C3G, making these therapeutic options, at least for the time being, necessary only in a subgroup of patients refractory to standard therapy.

Clinical Outcomes

Data on long-term outcomes, with the new classification, is limited for C3GN and DDD. Sethi, in a series of 12 of adult patients with C3GN, reported stable short-term renal function with a mean follow-up of 26.4 months [32]. Medjeral-Thomas, comparing outcomes of DDD and C3GN in a cohort of 80 patients, reported progression to ESKD in 47% of DDD patients and 23% of C3GN patients with a median follow-up of 28 months; there was no difference in cumulative renal survival by Kaplan-Meier analysis [116]. The French cohort of 134 patients reported 10 years renal survival of 63.5%, with no difference between groups (MPGN, DDD, and C3GN) [68]. These data support that from previous reports that progression to ESKD occurs in 40–50% of patients with MPGN regardless of type within 10 years of diagnosis. Analysis by both the French and English groups suggested that eGFR and age at presentation were strongly negatively correlated with long-term renal survival [68, 116]. Medjeral-Thomas also reported that presence of glomerular crescents or dense deposits by biopsy were independent predictors of disease progression [116]. Recently, a large retrospective study comprising 165 children with both IC-MPGN and

Table 5 Therapeutic agents targeting complement activity being evaluated for C3G/IC-MPGN. (Modified from [92])

Drug	Target	Mechanism	Clinical trial number
ACH0144471	Factor D	Prevents formation of C3 and C5 convertases	NCT03369236, NCT03459443, NCT03124368
LNP023	Factor B	Prevents formation of C3 and C5 convertases	NCT03832114, NCT03955445
APL2	C3	Prevents formation of C3 and C5 convertases	NCT03453619
AMY101	C3	Prevents formation of C3 and C5 convertases	NCT03316521
OMS721	MASP2	Blocks initiation of lectin pathway	NCT02682407
Avacopan	C5aR1	Blocks anaphylatoxin formation (C3a, C4a, and/or C5a)	NCT03301467

C3G confirmed that children have a better outcome than adults [177]. After a mean follow-up of 4 years, renal function was preserved, and at 10 years, 80% of children analyzed did not meet the composite outcome of eGFR <30 ml/min/1.73 m^2, 50% eGFR reduction, or need for kidney replacement therapy [177].

Disease recurrence of MPGN and DDD in transplants is frequent; data from the ESPN/ERA-EDTA registry shows an average renal allograft loss of 32.4% at 5 years posttransplant in children [178]. Data suggesting that pediatric patients with DDD are at greater risk of graft loss from disease recurrence has also been reported in the NAPRTCS database [179]. The reason(s) for the increased risk of recurrence in children is not clear. Several limited cases series confirm an increased risk of disease recurrence for C3GN and the potential negative impact on allograft survival. Zand et al. reported outcomes on 21 patients with C3GN, and 14 (66.7%) had disease recurrence with median time to graft failure of 77 months (6.4 years) [180]. The French group reported posttransplant recurrence rates of 43%, 55%, and 60% for MPGN, DDD, and C3GN, respectively [68]. The English group reported data on 13 transplants, 6 with DDD and 7 with C3GN. All DDD patients and four (57%) with C3GN had recurrence of disease; recurrence was strongly associated with graft failure [116]. The overall allograft survival at 5 years was 69%. FHR5-associated C3GN has also been reported to recur in renal transplants [181].

Future Perspectives

MPGN is now considered a pattern of glomerular injury and no longer considered a disease. The immunohistochemical findings sort cases into different categories. IC-MPGN is most common, and the underlying cause must then be established. Immune negative MPGN is next common; usually, the underlying cause is obvious as in chronic TMA, and posttransplant glomerulopathy. This new classification also recognizes significant recent advances in the understanding of the pathogenesis of C3-mediated glomerulopathy with the identification of a central role of the complement AP. This is reflected by the finding of C3 dominance in kidney biopsy specimens (further classified as C3 glomerulonephritis [C3GN] or dense deposit disease [DDD] depending on the pattern of the electron-dense deposits). It releases C3G from a strict relationship with MPGN in that a membranoproliferative pattern may or may not be present. Significantly, a proliferative and exudative pattern or a crescentic pattern may be as common as a membranoproliferative pattern. Given this shift in our understanding of the disease processes, we envision the elimination of the term MPGN. It will remain in descriptions and perhaps even in comments but will no longer be considered a disease.

C3 activation and generation of its split products has identified a specific and novel treatment strategy for this disease spectrum – blockade of C3 activation at the level of the AP C3 convertase – a potential breakthrough in disease management holding promise for improved patient outcomes in a group of diseases characterized by its progressively deteriorating nature.

Abstract

Thrombotic thrombocytopenic purpura (TTP) and hemolytic uremic syndrome (HUS) are thrombotic microangiopathies (TMAs) which are characterized by microangiopathic hemolytic anemia (MAHA) and thrombocytopenia and show significant overlap in clinical presentation but are distinct in their underlying pathology.

TTP is caused by an inherited or acquired deficiency in *a disintegrin and metalloproteinase with a thrombospondin type 1 motif, member 13* (ADAMTS13). ADAMTS13 cleaves von Willebrand factor (VWF) when released from endothelial cells, thus preventing the accumulation of prothrombotic ultra-large VWF (ULFWF) multimers. By difference, hemolytic uremic syndrome (HUS) is caused by infections with Shiga toxin (Stx)-producing *Escherichia coli* (*E. coli*; STEC HUS). And in the atypical form of HUS (aHUS), the endothelial injury is caused by complement dysregulation due to genetic (gain- or loss-of-function mutations) or autoimmune (inhibiting autoantibodies) causes. Recently, transient complement dysregulation has also been recognized in the absence of mutations and autoantibodies but rather as a consequence of infections, autoimmune diseases, drugs, mechanical endothelial injury, etc., thus defining a spectrum of secondary TMAs.

The advent of high precision medications which allow for the safe and efficient treatment of aHUS and TTP has fundamentally changed patient outcomes and quality of life.

Introduction

Thrombotic microangiopathies (TMAs) are a heterogeneous group of diseases that are characterized by microangiopathic hemolytic anemia (MAHA) and thrombocytopenia. TMAs occur ubiquitously but – for unknown reasons – most frequently affect the kidneys. While spanning a wide spectrum of underlying etiologies, pathomechanisms, and clinical presentations, all TMAs have the formation of microthrombi due to endothelial cell injury as a central pathologic feature in common.

Hemolytic uremic syndrome (HUS) is caused by infections with Shiga toxin (Stx)-producing *Escherichia coli* (*E. coli*; STEC HUS). In the atypical form of HUS (aHUS), the endothelial injury is caused by complement dysregulation due to genetic (gain- or loss-of-function mutations) or autoimmune (inhibiting autoantibodies) causes. Recently, transient complement dysregulation has also been recognized in the absence of mutations and autoantibodies but rather as a consequence of infections, autoimmune diseases, drugs, mechanical endothelial injury, etc., thus defining a spectrum of secondary TMAs.

By difference, thrombotic thrombocytopenic purpura (TTP) is caused by an inherited or acquired deficiency in *a disintegrin and metalloproteinase with a thrombospondin type 1 motif, member 13* (ADAMTS13). ADAMTS13 cleaves von Willebrand factor (VWF) when released from endothelial cells, thus preventing the accumulation of prothrombotic ultra-large VWF (ULFWF) multimers.

The advent of high precision medications which allow for the safe and efficient treatment of aHUS and TTP has fundamentally changed patient outcomes and quality of life. However, prohibitively high price levels seclude countries with limited resources from access to these medications – a scandalon, which to overcome remains an urgent task for the global medical community.

This chapter will review the different etiologies, clinical manifestation, management, and therapy of TTP, aHUS, and the so-called TMA spectrum of diseases. STEC-associated and other infection-associated HUS are reviewed in a separate chapter of this textbook.

Thrombotic Thrombocytopenic Purpura

Introduction

Thrombotic thrombocytopenic purpura (TTP) was first described in 1924 by Dr. Eli Moschcowitz [1]. He reported on a 16-year-old female presenting with unexplained fever, pallor, and petechiae. She developed unilateral weakness, followed by coma, and died a day after coma onset. On autopsy, diffuse arteriolar and capillary thrombotic occlusions were found, including the heart and kidneys; the brain was not examined. Initially termed Moschcowitz syndrome, the term TTP was proposed in 1947 [2].

It was initially assumed that TTP was an acquired condition (correct in the majority of cases); however, congenital disease was suspected in the 1960s with further research establishing this in the subsequent decades [3, 4], and given the eponym, Upshaw-Schulman syndrome (USS) in recognition. In these chronic relapsing patients, it was identified that plasma infusion would alleviate the thrombocytopenia and clinical features [3–6]. In 1982, Moake et al. reported their discovery of ultra-large VWF (ULVWF) multimers in patients with presumed hereditary TTP [7]. In 1996, two groups identified the VWF-cleaving protease [8, 9] and further analysis revealed this to be ADAMTS13 (*a disintegrin and metalloproteinase with a thrombospondin type 1 motif, member 13*) [10–13].

Pathophysiology

Hepatic stellate cells are the main source of ADAMTS13, with small amounts also produced in the endothelium [14]. It is released as an active enzyme in closed formation. To properly cleave VWF, its only substrate, multimers need to be unraveled by shear stress to expose A2 domains [15]. TTP is caused by a severe deficiency of ADAMTS13 either due to biallelic germline mutations in *ADAMTS13* or, more commonly, secondary to circulating autoantibodies. Deficient ADAMTS13 activity permits ULVWF multimers to circulate without proper cleavage, thereby causing diffuse platelet aggregation and microthrombosis [15, 16].

Congenital TTP (cTTP) is caused by homozygous or compound heterozygous mutations in the *ADAMTS13* gene on chromosome 9q34. Congenital disease comprises about a third of cases in children and 5% in adults [17]. Over 200 *ADAMTS13* mutations have been identified, without concentration in any specific domain for those diagnosed in childhood [18]. There are some mutations with greater frequency based on ancestry. The most common mutations in those of European descent are c.4143_4144dupA and p.R1060W, the latter of which is most prevalent (up to 1%) [19, 20]. Patients with cTTP and homozygous for p.R1060W have greater residual ADAMTS13 activity (5–10%); this is one of the most common mutations found in those presenting in adulthood, usually during pregnancy

[21, 22]. Immune-mediated TTP (iTTP) is caused primarily by neutralizing IgG anti-ADAMTS13 autoantibodies [23]; however, some antibodies are non-neutralizing and instead accelerate ADAMTS13 clearance [24, 25]. As opposed to cTTP, in which mutations are broadly distributed across the gene, anti-ADAMTS13 antibodies causing iTTP are primarily directed against the protease spacer domain [24, 26].

Diagnosis

In 1966, Amorosi and Ultmann proposed a "pentad" associated with TTP: thrombocytopenia, microangiopathic hemolytic anemia, neurologic symptoms, renal failure, and fever [27]. Though these features are variably present in TTP, they are not specific. Some are present in fewer than half of TTP cases, and a full pentad is uncommon, found in only <5% of cases [28]. Scores have been proposed, which predict severe ADAMTS13 deficiency and can help distinguish between TTP and other TMAs. The "French score" identified severe thrombocytopenia ($<30 \times 10^9$/L), serum creatinine <200 μmol/L, and positive anti-nuclear antibodies (ANA) as predictive. The presence of one or more criteria had an 85% positive predictive value, 93.3% negative predictive value, 98.8% sensitivity, and 48.1% specificity. With all three criteria met, the positive predictive value for severe ADAMTS13 was 98.7% [29]. In 2017, the seven-point PLASMIC score was proposed. Similar to the French score, platelets <30 x 10^9/L and non-severe renal involvement (creatinine <176.84 μmol/L) were found predictive; other criteria included MCV <90, INR <1.5, evidence of hemolysis (undetectable haptoglobin, reticulocytes >2.5%, and/or indirect bilirubin >2.0 mg/dL) and no history of bone marrow or solid organ transplantation [30]. A PLASMIC score of 6–7 denotes a high risk of severely deficient ADAMTS13 activity. The score was useful in pediatric patients as young as 3 years old [31], though a modification was proposed replacing MCV with the absence of bloody diarrhea [32].

TTP is confirmed by assessing ADAMTS13 activity, with severe deficiency (<10%) diagnostic in the appropriate clinical context. Most assays are ELISA and FRETS-based [33]. The presence of anti-ADAMTS13 antibodies can be assessed with ELISA or Bethesda assays, though the latter would miss non-neutralizing antibodies [25]. Antibodies may also be undetectable in iTTP if they are non-IgG, bound to ADAMTS13 forming immune complexes, or if the assay used is not sensitive. Persistent ADAMTS13 deficiency in the absence of autoantibodies suggests cTTP; for confirmation, *ADAMTS13* genetic analysis is required [34].

Management

Acute cases of immune-mediated or undifferentiated TTP should receive urgent therapeutic plasma exchange (TPE), which drastically improves survival [35]. One should not await results of the ADAMTS13 activity, which should be drawn prior to starting TPE. If there is to be any delay in transfer to an apheresis center, plasma infusion should be used to temporize. TPE should be provided daily at 1–1.5 plasma volumes with frozen plasma as a replacement until clinical response is achieved (sustained platelet count $>150 \times 10^9$/L, LDH $<1.5 \times$ ULN, and stabilization or improvement of end-organ involvement) [36]. Glucocorticoids are recommended if iTTP is suspected to decrease anti-ADAMTS13 antibody production [37]. Higher doses (e.g., 10 mg/kg) may have greater efficacy than the standard 1 mg/kg prednisone [38]; however, the use of high-dose pulsed methylprednisolone is often reserved for more severe presentations and must be balanced with possible greater toxicity.

Beyond prednisone, the anti-CD20 antibody, rituximab, is often used for immunosuppressive therapy. In many jurisdictions, it is available during the initial presentation, whereas in others approval is only granted for refractory or relapsed iTTP. Use is associated with shorter hospital stays, reduced TPE requirements, fewer relapses, greater time to relapse [39–42], and perhaps reduced mortality [43]. Other interventions can be considered for relapsed and refractory iTTP, including pharmacologic (e.g., cyclosporine, cyclophosphamide, bortezomib) and surgical options (e.g., laparoscopic splenectomy), though their benefit over rituximab is unclear [44]. Following the response to therapy, patients are monitored both clinically and by serial ADAMTS13 measurements, which should parallel clinical remission (Fig. 1). In those iTTP patients without ADAMTS13 normalization, vigilant monitoring is required to watch for relapse, particularly with exposure or reexposure to known triggers.

In cases of known cTTP, patients can be treated with plasma infusion instead of TPE. The volume of infused plasma per treatment is commonly 10–15 mL/kg, though some will use more (20–40 mL/kg) [45]; the patient's ability to handle such volumes must be assessed carefully. As with TPE, infusions should be continued until there is a clinical response. Beyond acute presentations, some patients with cTTP may require continued prophylactic/preventive infusions, typically every 2–3 weeks, based on platelet count and symptoms [19, 20]. More frequent infusions are often required during pregnancy, particularly following the first trimester [22, 46, 47]. The half-life of ADAMTS13 is 2.5–5.4 days [48–50]. Therefore, baseline activity will return approximately 5–10 days after each 10–15 mL/kg infusion [34, 50]. More recently, the use of recombinant ADAMTS13 has been shown effective and safe [51], with larger clinical trials ongoing at the time of writing.

A more recent addition to the TTP treatment arsenal is caplacizumab, a nanobody that targets

Fig. 1 Timeline and outcomes of acute episodes of iTTP. With or without a precipitating trigger, a patient can develop acute iTTP. Following diagnosis and appropriate treatment, most patients will reach clinical response, defined as normalization of platelet count and hemolytic markers with no evidence of new organ injury. After reaching clinical response, the majority of patients (about 80%) attain normal ADAMTS13 levels (ADAMTS13 remission) and enter remission. Approximately 20% will have a persistent deficiency and may experience an exacerbation. With intensified immunosuppression and time, most will achieve clinical and ADAMTS13 remission. A small minority (<5%) will have persistent ADAMTS13 deficiency and remain at a high risk of relapse, and may also experience silent disease progression. Not depicted: Approximately 40% of the patients who achieve clinical remission will experience at least one relapse in their lifetime. (Figure reprinted from Ref. [44])

the VWF A1 domain [52, 53]. Compared to placebo, its addition to the standard of care significantly shortened platelet normalization time and reduced exacerbations. Almost all recurrences seen in the phase 2 TITAN trial occurred in patients whose ADAMTS13 activity was still <10% [52]. The phase 3 HERCULES trial permitted the extension of daily subcutaneous caplacizumab beyond the initial 30 days if the patient's ADAMTS13 had not yet recovered [53]. Caplacizumab-treated patients in the HERCULES trial had a lower rate of a composite of TTP recurrence, death, and thromboembolic disease (12% vs. 49%), driven primarily by lower recurrence. The main side effect, seen in approximately half to two-thirds of patients, was mild-to-moderate mucocutaneous bleeding [52–54]. Successful and safe use of caplacizumab has also been reported in several cases of pediatric TTP [55–59]; however, no clinical trial data exist to date.

Complement and the Link to Disease

In the beginning of the twentieth century, the complement system was first identified as the heat-sensitive fraction of human plasma that "complemented" antibodies in their ability to kill microbes. More than 50 proteins that make up the three converging complement cascades were identified and characterized; their functions were limited to surveillance of microbial intruders and the propagation of immune and inflammatory responses. The antimicrobial properties of the complement system proteins were preserved over 500 million years of evolution [60]. The past decade has improved our understanding of the evolution of the complement system, and its cross-talk with other immune and thrombotic pathways (immuno-thrombotic continuum) [61, 62], homeostatic and intracellular activities [63–66], and association with a variety of diseases [67–71].

At its most basic level, the complement system is made up of three converging pathways of fluid-phase and membrane-bound proteins whose cascading activities progress in three stages: initiation, amplification, and termination. Initiation occurs when either pathogen- or damage-associated molecular patterns (PAMPs or DAMPs, respectively) are detected by surveillance proteins. The classical pathway is initiated when the C1 complex, made up of a C1q hexamer and two of each proenzyme, C1r and C1s, binds with an antigen-antibody complex. The conformational change that occurs upon binding causes C1r to autocatalytically cleave and in turn cleave the C1s proteins. The cleaved C1s proteins then perpetuate the activation by cleaving the next set of proteins, C2 and C4, into C2a + C2b and C4a + C4b. The final step of classical pathway initiation is the coming together of C2a and C4b. This complex binds to the cell surface of the antigen-antibody complex via C4b, and C2a provides the serine protease activity that will cleave C3 as a C3 convertase (C2aC4b) moves the classical pathway into the amplification phase.

The lectin pathway is initiated by contact with microbial carbohydrates via two protein families: ficolins (ficolin-1, ficolin-2, and ficolin-3) and collectins (mannose-binding lectin, collectin-10, and collectin-11). The structure of these proteins is a mirror image to that of C1q, and they interact with analogous proteins to C1r and C1s, MASP-1 and MASP-2, which also result in the cleavage of C2 and C4. The end result of the initiation of the lectin pathway is also a membrane-bound C3 convertase made up of C2aC4b.

The alternative pathway lacks a specific initiation phase and is constitutively active. However, it provides the substrates for amplification for all three pathways as they converge on the production of C3 convertases. The alternative pathway is continuously "ticking over" via spontaneous hydrolysis of C3 (Fig. 2), which yields the cleavage product C3a (an anaphylatoxin) and C3b (the major component of the downstream cascade). Normally, C3b binds indiscriminately to both pathogens and host cells. In combination with factor D (FD), C3b facilitates the cleavage of factor B (FB) to produce fragment Bb. Bb can then form a complex with C3b to generate yet another C3 convertase, namely C3bBb.

Activation of C3bBb results in a dramatic increase in the cleavage of C3 into C3a and C3b. Either prompted via the C3 convertase of the

Alternative Pathway

Fig. 2 **The alternative pathway of complement**. The alternate pathway of complement (AP) begins with spontaneous hydrolysis of C3 and the production of C3b. C3b combines with Bb to form the C3 convertase. The C3 convertase may go on to form the C5 convertase (C3bBbC3b) after the addition of another C3b or it may feedback to make additional C3b (the so-called amplification loop). C5 convertase will cleave C5 producing C5b, the first protein in the terminal complement complex. The ultimate products of the AP include two important anaphylatoxins (C3a and C5a) and the C5b-C9 complex. Factor H is the major regulator of the AP, and dysregulation of FH is the most common genetic cause of aHUS. (Figure created with BioRender.com)

classical and lectin pathways (C2aC4b) or the C3 convertase of the alternative pathway (C3bBb), it is this step in the alternative pathway that is designated the amplification loop. The cleavage of C3 will beget more Bb and more C3 convertases.

A small portion of the C3 convertases moves forward in the pathway to the termination stage. They do so by forming the C5 convertase (C3bBbC3b) via the addition of an additional C3b to the existing C3Bb complex. The C5 convertase in turn is responsible for cleaving C5 into C5a (another potent anaphylatoxin) and C5b (the first protein in the terminal complement complex). C5b binds to C6, C7, C8, and C9b to form the membrane-attack complex (MAC). Activation of the alternate pathway and formation of MAC causes irreparable cellular damage and is an efficient line of defense against a variety of pathogens.

In contrast to the coagulation cascade, there are no products in the complement cascade that provide negative feedback. Complement activation and amplification are only controlled by the presence of a number of regulatory proteins. The classical and lectin pathways are regulated by the C1 inhibitor binding to C1r/C1s or the MASP proteins, respectively. There are many regulators of the amplification loop, including an array of membrane-bound or soluble proteins that irreversibly dissociate the C3 and C5 convertases (decay-accelerating factor, complement receptor 1, factor H and factor H-like protein 1, C4 binding protein) or act as cofactors for factor I-mediated degradation of C3b and C4b (membrane cofactor protein, factor H, complement receptor 1, C4 binding protein) [72, 73]. Clusterin, vitronectin, CD59 and CUB, and Sushi multiple domains 1 (CSMD1) disrupt the termination stage by preventing MAC assembly [74]. Human disease is observed when there is an imbalance of positive or negative regulators of the complement system [69].

These pathways have been considered to proceed autonomously in the systemic circulation with proteins produced by the liver. It is now well established that their functions are simultaneously more expansive and local. For example, in addition to initiation of the classical cascade, C1q has many immunoregulatory functions, including enhancing phagocytosis of apoptotic and cancerous cells, regulating cytokine production by antigen-presenting cells, and altering T-lymphocyte maturation [75]. C1q also plays a critical role in many physiologic and pathologic processes, ranging from fetal development and pregnancy to tissue repair and central nervous system homeostasis [75]. MASP-1 of the lectin pathway has been described as "promiscuous" interacting with numerous substrates and inhibitors, including fibrinogen, factor XIII, and prothrombin and antithrombin from the coagulation cascade [76]. MASP-1 also can increase inflammation via binding to proteinase-activated receptors on endothelial cells and enhancing bradykinin release. Similarly, proteins of the coagulation cascade directly affect the complement cascade. Thrombin, plasmin, kallikrein, and factors XI, X, and IX might cleave C3 and C5 directly, albeit less efficiently compared to the convertases [77]. Thus, the cascades are intertwined with other immunothrombotic surveillance systems. Contrarily, at the intracellular and local levels, it has been established that most nucleated cells produce a variety of complement proteins called the *complosome*, which performs cell-modulatory functions [78]. Thus, traditional cascades are just one piece of the overall effect each complement protein has on both health and disease.

It is within this complex and evolving context that we then consider the means by which complement contributes to disease. These mechanisms have been aptly simplified into four categories: excessive activation (hyper-acute inflammatory process, such as sepsis), misdirected activation (response to a biomaterial, such as a renal transplant or dialysis filter membrane), insufficient regulation (genetic mutation in or antibody against a regulatory protein) or, in rare cases, unwarranted regulation (immunologic evasion of tumors and pathogens) [69]. Given the pervasiveness of these proteins, diseases can be local or systemic, and depending on the trigger, can be acute or chronic.

Specific to pediatric nephrology, complement dysregulation typically manifests as thrombotic microangiopathy, which is characterized by thrombocytopenia, microangiopathic hemolytic anemia, and organ injury, including acute kidney injury. Clinical findings fell into three categories: illness with a severely low ADAMTS13 and neurologic changes (thrombotic thrombocytopenic purpura, TTP), HUS in presence of Shiga toxin-producing *Escherichia coli* (STEC-HUS), and broadly all other causes of TMA (atypical HUS). This nomenclature has evolved in parallel with our understanding of the complement system and the molecular bases of TMA. Multiple similar schemas have been introduced [68, 79–82]. Another classification includes: (i) complement-mediated primary TMA, either inherited or acquired via autoantibodies, (ii) secondary TMA due to coexisting conditions, and (iii) infection-associated TMA.

Atypical HUS

Epidemiology

Most experts agree that aHUS accounts for ~5% of all patients presenting with the clinical findings of HUS. Being an ultra-rare disease, it is challenging to calculate the exact incidence of aHUS. It is presumed to be approximately two cases per one million population by extrapolating from the number of cases of non-TTP and non-Shiga toxin HUS, most of which are presumed to be due to aHUS [83]. Incidence based on European data is as high as seven per million children [84]. These are likely underestimations of the true incidence since we now know that aHUS patients can present with prodromal diarrhea [85]. On that basis, terminologies diarrhea-positive (D+) and diarrhea-negative (D-) were phased out in the past ~10 years [86]. Formerly considered as a disease of children, it is now clear that aHUS affects both children and adults approximately equally [85–89]. Males and females are equally represented in all studies. A few factors increase the likelihood that a patient with a new clinical diagnosis of HUS will ultimately be confirmed to have aHUS: presentation before ~12 months of age [90, 91], positive family history of HUS (in up to 30% of aHUS patients) [88], and history of consanguinity.

Clinical Features

Patients with aHUS often present suddenly, with many constitutional symptoms including fatigue and anorexia. Families often report a preceding illness, particularly a respiratory illness or a gastrointestinal infection (causing non-bloody diarrhea) [85, 89, 93–98]. The tight relationship of aHUS episodes with various triggering infections may initially suggest other forms of HUS (e.g., STEC or pneumococcal HUS), leading to diagnostic confusion and delays to implement effective therapies.

The classic diagnostic triad of TMA is usually evident at the initial presentation. Pallor due to the microangiopathic hemolytic anemia is usually noted. A bleeding diathesis may be documented, linked to ongoing thrombocytopenia. Manifestations of acute kidney injury (AKI) are common, including hypertension, decreased urine output, and edema [88, 89]. It is important to acknowledge that in 10–20% of patients, bona fide aHUS can present without thrombocytopenia: “partial aHUS” invariably has evidence of microangiopathic hemolysis and AKI, and clinical outcomes are similar to that of patients with “full aHUS” [99].

While the kidneys are the primary target in all forms of aHUS, extrarenal involvement is present in 20–50% of patients [100]. The range of extrarenal organs affected in patients with aHUS closely overlaps with that reported for patients with STEC HUS [101]. The most frequent extrarenal symptom is seizures, but other neurologic abnormalities may also be observed (diplopia, blindness, paresis, coma). Prompt neuroimaging is invaluable to discern if these events are due to CNS thrombosis or a result of underlying kidney pathology (e.g., posterior reversible encephalopathy syndrome, PRES) [102]. Cardiac dysfunction, including pericardial effusion or myocardial infarction, has been reported [103]. Gastrointestinal involvement may occur in the form of hepatitis, pancreas necrosis, and/or ischemic colitis [100]. Vasculopathies of peripheral limbs or the retina are rare [100].

Pathophysiology

The major abnormality observed in aHUS is a form of TMA that primarily affects the blood vessels of the kidneys. Histologically, this process is indistinguishable from the pathology documented in other forms of HUS. It remains unclear why such a diverse array of HUS subtypes all exhibit exquisite tropism for the kidney microvasculature: it may be due at least in part to the stress generated by the unique rheological properties of glomerular capillaries (high flow, high pressure). TMA lesions are initiated when a severe injury to glomerular capillaries of multiple vascular beds at once triggers repair mechanisms that lead to a local prothrombotic environment.

The trapping of platelets in the microthrombi explains thrombocytopenia. Microangiopathic anemia is due to the shearing of erythrocytes as they transit through the partially obstructed glomerular capillaries. The initiating factor in most (but not all) patients with aHUS is related to abnormal activity of the alternative pathway (AP) of the complement system, which in turn leads to a strong immune attack of glomerular endothelial cells. In contrast, the pathophysiology of most complement-independent forms of aHUS is poorly understood. Discoveries related to the genetic or autoimmune causes of aHUS have been invaluable to devise therapies that address the underlying pathophysiology.

Genetics

Most reviews on aHUS suggest that ~60% of patients diagnosed with aHUS have a pathogenic genotype [104]. Of interest, a recent study on more than 3100 aHUS patients from 6 major centers reported that only ~40% had a mutation in one of the major aHUS genes [105]. The true yield of current genetic testing panels for aHUS is likely between those two figures. There is no doubt that clinicians should consider including a genetic testing panel in their early management care plan. Indeed, genetic testing results will help predict the overall prognosis and response to established therapies, determine the optimal timing of eculizumab discontinuation, and plan for suitable pre- and post-transplant precautions [68]. Below, we first discuss the major forms of genetic aHUS associated with complement abnormalities, followed by a presentation of the most salient genetic aHUS subtypes that cause pathology independent of the complement.

Genetics Forms of Complement-Mediated aHUS

Pathogenic variants in a host of complement genes are often identified when investigating patients with aHUS (e.g., *CFH*, *CFI*, *CFB*, *C3*, *MCP*, *CFHR5*). The mutation identified conspires to enhance the activity of the alternative complement cascade. As such, genes encoding negative regulators of the complement are expected to harbor variants that cause loss-of-function (*CFH*, *CFI, MCP*), whereas positive regulators have gain-of-function variants (*C3, CFB*).

The genetics of complement-driven aHUS is very complex because it includes allelic heterogeneity (different variants in the same gene lead to similar phenotype), locus heterogeneity (variants in different genes lead to similar phenotype), and mode-of-inheritance heterogeneity (heterozygous or homozygous variants in the same gene can cause the same disease) [106]. Importantly, three genes also exhibit phenotypic heterogeneity since variants in *CFH*, *C3*, or *CFHR5* can cause not only aHUS but also C3 glomerulopathy (a phenotypically distinct disease). Also, most of these conditions exhibit incomplete penetrance (a given variant is observed in affected and non-affected relatives) and/or variable expressivity (all relatives with a given variant are affected by the same disease with a wide spectrum of severity) [106].

CFH-Associated aHUS

Complement factor H is one of the major negative regulators of the alternative complement system: it controls the formation of C3b in the fluid phase (Fig. 2) [107]. The discovery of mutations in *CFH* provided the first proof of the existence of a genetic form of aHUS [108]. Mutations in *CFH* are the most frequent pathogenic genotype identified in aHUS patients: it occurs in ~40% of aHUS patients with a confirmed molecular diagnosis (Fig. 4) [105]. Patients with homozygous *CFH* mutations typically present in infancy with severe disease whereas patients with heterozygous mutations present at any age with milder forms of aHUS [109]. All pathogenic *CFH* genotypes either lead to decreased production of CFH proteins or to the production of a nonfunctional form of CFH [88].

MCP-Associated aHUS

Membrane cofactor protein (MCP, also known as CD46) is a cell surface negative complement regulator: it functions as a cofactor for FI, thereby assisting with C3b degradation (Fig. 2) [107]. The link between *MCP* mutations and aHUS was first established in 2003, with ~75% of kindreds exhibiting incomplete penetrance in the context of a heterozygous mutation [110, 111]. More severe disease is associated with recessive *MCP* mutations or heterozygous *MCP* mutations accompanied by another mutation in one of the complement genes [112]. Pathogenic mutations in *MCP* are reported in ~16% of aHUS patients with a confirmed molecular diagnosis (Fig. 4) [105]. They lead to either decreased amounts of MCP proteins on the cell surface or to impaired ability to regulate complements at the surface of endothelial cells [96]. On that basis, the risk of post-transplant recurrence would be predicted to be low: the higher observed rates are due to the repopulation of the allograft vasculature with recipient endothelial cells, a phenomenon known as endothelial microchimerism [113].

CFI-Associated aHUS

Factor I (FI) is the third major negative regulator of the complement system (Fig. 2) [107]. It was therefore not surprising when two teams reported that *CFI* was frequently mutated in patients with aHUS [114, 115]. Incomplete penetrance and variable expressivity are the norms for *CFI*-associated aHUS. Recent data suggest that ~10–15% of aHUS patients have a heterozygous *CFI* mutation (Fig. 4) [105]. Like in *CFH*-associated aHUS, a *CFI* mutation leads to low CFI protein levels or reduced enzymatic activity, thereby causing higher activation of the alternate pathway [116].

C3-Associated aHUS

Complement component 3 (C3) is central to the alternative complement cascade as it is the substrate required to generate the bioactive fragments C3b and C3a (Fig. 2) [107]. Pathogenic heterozygous *C3* mutations, which were first reported in 2008, resulting in a gain-of-function phenotype by preventing the degradation of C3b (e.g., via reduced binding to CFH or MCP) [117]. In some rare cases, the gain-of-function phenotype is due to enhanced C3 binding to CFB [118]. About 10–15% of aHUS patients harbor C3 mutations (Fig. 4) [105, p. 201].

CFB-Associated aHUS

Cleavage of factor B (FB) by factor D (FD) is necessary for the production of C3 convertase, C3bBb (Fig. 2) [107]. On that basis, gain-of-function *CFB* mutations were predicted to cause disease, and this is precisely what was found: heterozygous *CFB* mutations caused either enhanced formation or delayed the decay of C3 convertases [119]. It is now clear that this is a rare form of aHUS, accounting for ~2–4% of all confirmed cases of aHUS (Fig. 4) [105, p. 201]. FB-associated aHUS are generally fully penetrant [120], but kindreds consistent with incomplete penetrance are also described [119].

Thrombomodulin-Associated aHUS

Although previously mostly known as a cofactor for thrombin, preventing blood coagulation [121], thrombomodulin (THBD) was subsequently demonstrated to regulate FI-dependent degradation of C3b [122]. These studies were triggered by the discovery of an association between heterozygous *THBD* mutations and aHUS more than 10 years ago [122]: *THBD* mutations now account for ~1–2% of aHUS patients (Fig. 4) [105]. There is also some evidence linking *THBD* mutation with increased risks of venous thrombosis or myocardial infarction [123]. The pathophysiology of this condition may be due to the combined disturbances of the complement system and the coagulation cascade. More data is needed to make robust inferences regarding long-term outcomes or the impact of complement-based therapies.

Genetic Forms of aHUS Unrelated to Complement

Mutations in genes, that are not a component of the alternate pathway, have been reported to cause aHUS. These include cobalamin C (*cblC*) [124], diacylglycerol kinase epsilon (*DGKE*) [125], and plasminogen (*PLG*) [126]. There is currently no clear evidence that therapies targeting the alternate pathway are effective for the above conditions unless patients also carry a mutation in one of the complement genes. It also is unclear if these genes play a role through their interaction with complement or whether a coagulation protein-specific mechanism is involved. It is possible that additional research will uncover hitherto unknown physiologic roles for the products of these genes in the regulation of the complement system.

Cobalamin C Deficiency-Associated aHUS

With only ~40 cases reported since 1992, cobalamin C (cblC) deficiency-associated HUS is a rare form of TMA [127, 128]. This autosomal recessive condition is caused by mutations in the gene encoding for methylmalonic aciduria and homocystinuria type C protein (*MMACHC*) [124, 129]. Patients with this condition typically present as neonates with failure to thrive, neurologic symptoms, and features of TMA [127]. A subset of patients present as teens [127], and adult-onset is unusual [130]. High mortality has been reported for infantile *clbC*-associated HUS [127, 131]. The diagnostic hallmarks are hyperhomocysteinemia, low blood methionine, and methylmalonic aciduria [132]. Patients are usually treated with a combination of hydroxocobalamin, folinic acid, and betaine [133]. The impact of this cocktail on neurologic and vascular pathology is variable.

Several mechanisms are proposed to explain the TMA lesions, including endothelial damage induced by hyperhomocysteinemia or impairment of nitric oxide-dependent inhibition of platelet aggregation [127, 132].

DGKE-Associated aHUS

First reported in 2013 [125], *DGKE*-associated aHUS is one of the most common forms of aHUS diagnosed in children less than 2 years old. Patients with this condition experience TMA recurrences until 5 years of age (usually triggered by infection), have increasingly worse hypertension and proteinuria with age, and develop ESKD between the ages of 10 and 25 [134, 135]. The clinical features do not improve with eculizumab, and there are no documented cases of post-transplant aHUS recurrence. There are now more than 60 patients diagnosed with this ultra-rare condition [134, 135]; patients with DGKE nephropathy account for ~4–5% of all aHUS patients (Fig. 4) [105]. Patients with recessive pathogenic genotypes show almost complete deficiency of DGKE activity [134]. While most patients have clear loss-of-function *DGKE* variants (nonsense, frameshift, splice site), about ~30% have missense *DGKE* variants [134]. About 5–10% of patients with clearly pathogenic *DGKE* genotypes present with an active glomerulopathy, but without findings of TMA [136], a phenomenon that remains unexplained. While the exact pathophysiology remains elusive, it appears that *DGKE* deficiency causes endothelial cell activation [137], perhaps by interfering with prostaglandin E2 production [138] or signaling by vascular endothelial factor receptor-2 [139].

Plasminogen-Associated aHUS

Since thrombosis is central to TMA, a group of patients with undiagnosed aHUS were screened for mutations in all major genes implicated in the coagulation pathway using targeted exome sequencing [126]. The most notable finding was that 3/36 patients had heterozygous plasminogen (*PLG*) variants, all of which were known to cause *PLG* deficiency in the homozygous state. A recent study revealed that ~1% of patients with aHUS have a *PLG* variant (Fig. 4) [105]. In principle, *PLG* deficiency could reduce thrombi degradation, leading to a prothrombotic state [140]. The same question was the subject of intense investigations 20 years ago for patients with venous thromboembolism: the overwhelming conclusion was that heterozygous *PLG* deficiency is a benign condition [141]. It remains to be established whether *PLG* variants are causal, or act as a risk factor, for aHUS.

Autoimmune Forms of aHUS

The discovery that mutations in many complement genes caused aHUS led to the hypothesis that autoantibodies directed against the complement proteins could perhaps trigger an autoimmune form of aHUS [142, 143]. In 2005, investigators provided the first demonstration that anti-FH autoantibodies were present in a subset of patients with aHUS, resulting in an acquired functional FH deficiency [144]. The antibodies either reduced serum FH levels or interfered with the binding of FH to C3 convertase [144–146]. Of interest, most patients with anti-FH autoantibodies have homozygous deletions of *CFHR1* and *CFHR3*, suggesting that the gene deletions may play a role in the development of autoantibodies [147–149]. The functions of FHR proteins and their role in autoantibody production is not well understood [150]. In addition, in aHUS patients, anti-FI autoantibodies were found which also cause activation of the complement system [151]. Anti-FH and anti-FI autoantibodies typically account for ~10–25% and ~2% of aHUS cases, respectively, except in India, where anti-FH autoantibodies are the chief cause of aHUS and occur in ~55% of aHUS patients [152], and anti-FI autoantibodies are found in ~30% of patients [153]. Interestingly, anti-C3 autoantibodies enhancing the activity of the (alternative pathway) C3 convertase upon binding (so-called C3 nephritic factor, C3NeF) are found in patients with C3G, but have not been reported as a cause of aHUS [154].

Patients with autoimmune HUS often show a relapsing course [152, 155]. Higher titers of FH antibodies have been associated with a high risk of relapse [152]. Treatment guidelines recommend either prompt initiation of therapy with PLEX and immunosuppression or eculizumab with immunosuppression [82, 93, 156]. Treatment should be guided by FH antibody titers and once undetectable for at least 6 months KDIGO suggests that treatment could be discontinued [93]. There has been no study to compare the efficacy of eculizumab vs. PLEX. Several case reports report successful use of eculizumab either after failed PLEX or as initial treatment [157, 158]. Five to seven PLEX sessions achieve 80% reduction in antibody titers [159]. Immunosuppressive therapy mainly includes steroids plus either mycophenolate mofetil, cyclophosphamide, or rituximab [155, 156, 160, 161]. There is no data available that favors one over the other, and the choice of immunosuppression will depend on treatment availability and how comfortable clinicians feel with either treatment option. Overall outcome has been good for patients with FH antibody-associated aHUS if treated with PLEX/eculizumab and immunosuppression. However, kidney failure has been reported in about 10–25%. Late initiation of treatment is associated with worse outcomes [152, 157, 160].

Diagnosis

The diagnosis of aHUS is clinical and based on clinical features and absence of other disorders. There are no specific labs that will aid in the diagnosis of aHUS acutely. As previously mentioned, the presentation with the triad is nonspecific. It is necessary to exclude TTP by ruling out a functional abnormality or mutations in *ADAMTS13*. It is also critical to rule out STEC-associated HUS, especially if the patient presents with diarrhea. Circulating C3 and C4 complement assays are not useful since only 30–40% of patients with aHUS [85, 89, 162, 163] will have abnormal levels. Decreased plasma levels of FH or FI are seen in ~50% and ~30% of patients with significant variations in *CFH* or *CFI*, respectively [85, 164]; assays to quantify these proteins are not widely available. It is important to emphasize that normal serum C3 levels do not rule out aHUS, and that mutant *CFH* or *CFI* may be associated with normal plasma levels. The presence of high soluble C5b9 levels in serum is perhaps a useful indicator of disease activity but has drawbacks (high cost, not widely available, lack of assay standardization) [165].

While genetic testing with current aHUS gene panels is invaluable to distinguish aHUS subtypes, a detailed report is available only after a few weeks. Furthermore, in ~40–60% of cases, a significant variation might not be detected [85, 89, 162, 163]. Genetic studies, however, are necessary to guide subsequent treatment and are useful for long-term management. Current aHUS genetic testing panels include *CFH*, *CFI*, *MCP*, *C3*, *CFB*, *CFHR5*, *THBD*, and *DGKE*. The detection of hybrid *CFH* genes and copy-number variations in *CFH* or *CFHR1–5* are done using multiplex ligation-dependent probe amplification (MLPA) [166]. Investigations for anti-FH antibodies should also be performed. Patients with findings consistent with cobalamin C deficiency should undergo detailed biochemical characterization and genetic testing for *MMACHC* mutations (Fig. 3).

Management of aHUS

As with all renal diseases, management should include optimal management of hypertension, proteinuria, and attention to the effects of acute or chronic kidney disease in the child. Historically, the mainstay of treatment of aHUS has been the institution of plasma therapy (either infusion or exchange). The theory behind the use of either of these interventions hinges on the concept of either removing an abnormally functioning protein or replacing a deficient one. Treatment efficacy for plasma was based on the initial reports of success in FH-related diseases [89]. Consensus guidelines have suggested that plasma exchange be instituted as soon as possible after the diagnosis of aHUS, using 50–100 mL/kg of plasma per session [167]. The recommendation was for PE to be performed daily and the dose titrated to

Autoantibodies: Factor H autoantibody
Genetic complement assessment

Fig. 3 Diagnostic algorithm for thrombotic microangiopathy (TMA). Diagnosis of a complement-mediated disease starts with recognition of thrombotic microangiopathy (TMA), which includes thrombocytopenia, microangiopathic hemolytic anemia (MAHA), and organ injury, including acute kidney injury (AKI). TMA can be differentiated from disseminated intravascular coagulation (DIC) by abnormal coagulation times. ADAMTS13 should be sent urgently to evaluate for thrombotic thrombocytopenic purpura (TTP). Evaluation for infection-associated and secondary TMAs should be investigated in tandem with complement-mediated TMA, and therapy should be initiated promptly while workup is underway. *BMT* bone marrow transplant-associated, *ECG* electrocardiogram, *STEC-HUS* Shiga toxin-producing *Escherichia coli* hemolytic uremic syndrome [65, 68, 82, 92, 93]

control hemolysis. Once hemolysis was controlled, the frequency of PE was reduced and then discontinued.

Noris et al. reported that plasma therapy resulted in complete or partial remission in 78% of aHUS episodes in children and 53% in adults. Looking closer at this single cohort however revealed that despite hematologic improvements, 48% of children and 67% of adults either died or reached end-stage renal disease (ESRD) at follow-up [89]. It has become apparent that plasma therapy may be reasonably successful at improving hematologic parameters but is not uniformly successful at facilitating renal health. The lack of availability of an alternative therapeutic regimen in some settings and comfort with the delivery of this care ensures that plasma therapy will continue to be used per local custom.

Given the current understanding about the pathophysiology of aHUS, complement blockade has become the gold standard for the treatment of this disease. Eculizumab, a monoclonal humanized anti-C5 antibody, prevents C5 cleavage and formation of both C5a and C5b-9. Therefore, eculizumab therapy can reduce anaphylatoxin-induced inflammation and limit C5b-9 prothrombotic consequences of complement activation. Trial data supports the efficacy of weight-based dosing of this agent [168] in the treatment of aHUS, and eculizumab is now approved for the treatment of aHUS both in the United States and in Europe (Table 1). An eculizumab concentration of 50–100 μg/mL will typically produce complete complement blockade in patients with aHUS [165, 169]. While drug level monitoring is not routinely practiced, it has been used to tailor medication dosing in patients with severe or atypical diseases [170, 171], and to reduce unnecessary drug utilization [172].

Whenever possible, eculizumab should be started as rapidly as possible in all children with aHUS at a standard dose. Vaccination status should be evaluated for all meningococcal strains and for *Streptococcus pneumoniae* and *Hemophilus influenzae*; these vaccinations are completed as soon as possible, and subsequently kept up to date during prolonged complement blockade. If vaccination is not possible or until 15 days after it is completed, antibiotic prophylaxis against meningococcal infection must be administered. Moreover, in children <5 years of age, in immunosuppressed individuals, and in those who live in communities, low-dose prophylactic antibiotics may be advisable even with a complete vaccination schedule. Patients receiving anti-C5 treatment should be advised of the risk of meningococcal infection, albeit low, instructed on early identification of warning signs and symptoms, and provided with an information card to carry at all times allowing for prompt recognition of their disease and treatment upon hospital admittance [82].

A long-acting form of eculizumab, ravulizumab, has been assessed both in paroxysmal nocturnal hematuria and in aHUS and has been shown to effectively control the disease while allowing less frequent infusions both in adults with aHUS [173] and in children previously treated with eculizumab [174].

Treatment with anti-C5 (eculizumab, ravulizumab) or with other complement-blocking agents that are currently being evaluated is not a disease-modifying approach, as it does not eliminate the underlying complement dysregulation in patients with aHUS. Barring forms driven by anti-FH antibodies, where standard immunosuppression can lower these antibody titers to the extent that it eliminates the driver of disease, and forms due to *DGKE* mutations which are complement-independent, in all other forms of aHUS due to alternative pathway of complement dysregulations, interrupting this treatment entails a variable degree of risk of disease recurrence. Therefore, if, how and when to discontinue anti-complement therapy is a difficult issue that does not have a single answer. Elements that must be considered are the presence and type of complement mutation, which determines the degree of risk, together with the morbidity of prolonged repeated intravenous infusions, risk of meningococcal infection, and especially in some settings the elevated costs of both the treatment and the infusions.

Special consideration is required for patients with aHUS triggered by autoantibodies. Many authors have reported that the risk of having a recurrent disease in this setting is based on the anti-FH antibody titers if there are no complement mutations identified. Therefore, it has been proposed that, in addition to anti-complement therapy at disease presentation, an acceptable treatment plan for antibody-mediated aHUS includes an antibody reduction strategy. This entails either use of plasma exchange or therapy with immunosuppressive medications (cyclophosphamide, rituximab, or mycophenolate mofetil) in order to reduce the antibody titer to a safe level. No trials are available to support this approach and the level of antibody titer may be lab dependent, therefore defining a “safe” threshold is challenging. Moreover, the length of eculizumab treatment required in these forms is still unclear.

Long-Term Complications

Prior to the introduction of anti-complement therapy, the prognosis for aHUS patients was poor. The 1-year mortality was reported to be as high as 6.7% in affected children, while end-stage kidney disease (ESKD) occurred in up to 16% [88]. At 5 years’ follow-up, 48% of children had reached ESKD.

Undoubtedly prognosis varies within genotype subgroups (Fig. 4). Individuals with *MCP* mutation carry the best prognosis [89]. Mutations in *CFH*, *CFI*, and *C3* show unsatisfactory outcomes. The first-episode mortality in children with *CFH* mutation was 30% [89] and evolution to ESKD in survivors was up to 33% in children [88]. Similarly, up to 60% of individuals with *CFI* or *C3* mutations reached ESKD or death at 5 years. At 5-year follow-up, 77% of patients with *CFH* mutations had developed either ESKD or death.

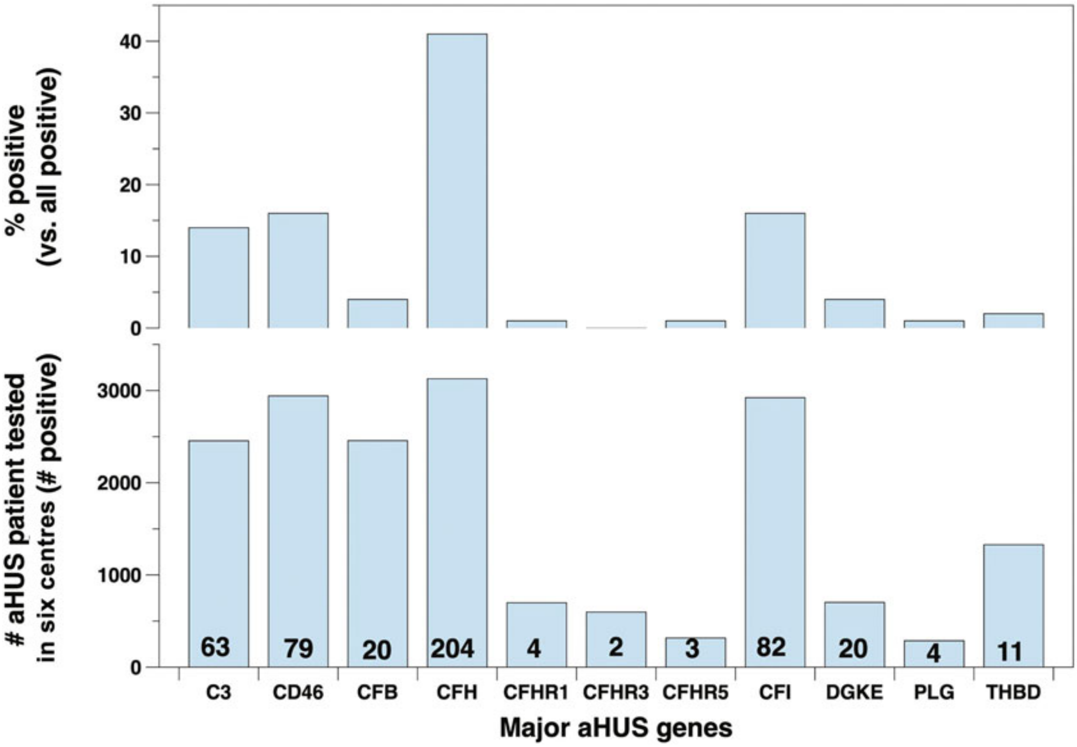

Fig. 4 Yield of genetic testing for a large cohort of patients with clinical features of aHUS. The data presented is from Osborne et al. [105], which collated genetic testing results from 3108 patients from six centers. The top panel illustrates the percentage of positive tests for given aHUS genes when compared to all positive tests. The bottom panel shows that the number of times each gene was tested is quite variable. It also shows how many patients harbored a variant in a given gene (numbers in bold).

Table 1 Weight-based dosing of eculizumab

Patient body weight	Induction regimen	Maintenance regimen
40 kg and over	900 mg weekly × four doses	1200 mg at week 5; then 1200 mg every 2 weeks
30 to <40 kg	600 mg weekly × two doses	900 mg at week 3; then 900 mg every 2 weeks
20 to <30 kg	600 mg weekly × two doses	600 mg at week 3; then 600 mg every 2 weeks
10 to <20 kg	600 mg weekly × one dose	300 mg at week 2; then 300 mg every 2 weeks
5 to <10 kg	300 mg weekly × one dose	300 mg at week 2; then 300 mg every 3 weeks

Thirty-three percent of children were likely to evolve to ESKD after the first episode. Up to 60% individuals with *CFI* or *C3* variations experienced ESKD or death. These statistics have significantly improved, in adults and children, with the advent of anti-complement therapy, with a maximum of 10–15% of patients in ESKD at 1-year follow-up irrespective of the mutation [175].

As mentioned, children with aHUS often have extrarenal symptoms. Long-term complications are similar to those seen in severe STEC HUS and include permanent renal injury and metabolic derangement, cardiac and gastrointestinal abnormalities, and occasionally residual neurologic disease.

Transplantation

Prior to the era of anti-complement therapy, the likelihood of aHUS recurrence in an allograft was entirely dependent on the causal mutation. Le Quintrec et al. [176] reported that aHUS patients had a 5-year graft survival of only 51% and this was associated with a 5-year mortality of 7%. *CFH*-related aHUS was most likely to recur in almost 90%, followed by *C3*, *CFB,* and *CFI* (50% recurrence risk). In contrast, post-transplant recurrence occurs in less than 10% of patients with *MCP* mutation. Post-transplant recurrence has also been observed in five patients with *DGKE* mutation. The recurrence risk is low in anti-FH antibody-associated HUS, as long as antibody titers are low.

It is generally accepted that aHUS patients may require some combination of plasma therapy and/or eculizumab prior to and post-transplant; however, protocols vary and prophylactic treatment should be based on the risk of recurrence. PE/PI for post-transplant recurrence generally failed to prevent graft loss. Therefore, prophylactic PE/PI (started just before transplantation) has been recommended [112] and should be used when anti-complement therapy is not available. Whenever possible, anti-complement therapy should be used to prevent recurrence starting just prior to renal transplantation in all forms of aHUS based on quantification of the risk of recurrence [93].

Briefly, high-risk patients are defined as those with a previous recurrence of aHUS on a renal allograft, or harboring pathogenic variants of *FH*, *C3,* or *FB* genes; moderate risk are patients with a negative complement screening or with a pathogenic variant in *FI* gene or with detectable circulating anti-FH antibodies; low-risk patients are those with undetectable circulating anti-FH antibodies who previously were positive and patients harboring *MCP* or *DGKE* isolated mutation. The use of prophylactic eculizumab starting immediately prior to transplant in patients with a moderate and high risk of recurrence was shown in a large retrospective study to significantly decrease aHUS recurrence and to significantly increase graft survival even compared to patients in whom recurrence was promptly treated with eculizumab, and it was also shown to have dramatically increased the numbers of renal transplants successfully performed in this patient population [177]. These data compellingly indicate that this is the correct strategy in aHUS patients with a moderate or high risk of recurrence.

Spectrum of Thrombotic Microangiopathy (TMA)

Introduction and Nomenclature

Thrombotic microangiopathy has been associated with several underlying conditions and historically this form of TMA was termed secondary HUS [82, 93]. A list of conditions that have been repeatedly associated with TMA are listed in Table 2. In the last two decades, researchers have started to

Table 2 Spectrum of disorders associated with thrombotic microangiopathy (TMA)

Pregnancy-associated TMA (pTMA)
Post hematopoietic stem cell transplant-associated TMA, or transplant TMA (TA-TMA)
TMA post solid organ transplantation
TMA associated with metabolic disease: Cobalamin C deficiency
TMA associated with systemic autoimmune diseases • Systemic lupus eythematosus • ANCA-associated vasculitis • Antiphospholipid syndrome • Systemic sclerosis • Mixed connective tissue disorder • Sjögren syndrome • Inflammatory bowel disease
TMA associated with drugs • Quinine • Anti-VEGF inhibitor • Chemotherapy such as gemcitabine, mitomycin, and cisplatin • CNI inhibitors
TMA associated with malignant hypertension
TMA associated with infections • Bacteria associated with a gastrointestinal infection, such as Shiga-toxin producing *E. coli*, *Shigella dysenteriae*, *campylobacter jejuni*, *Moraxella osloensis* • Viruses, such as cytomegalovirus, Epstein-Barr virus, varicella zoster virus, parvovirus B19, human immunodeficiency virus, influenza • Bacteria causing respiratory tract infections, such as *Bordetella pertussis*, *Streptococcus pneumoniae*, *Mycoplasma pneumoniae*, COVID-19 • Fungal infections in immunocompromised hosts
TMA associated with other renal diseases • C3 glomerulopathy • IgA nephropathy

investigate the underlying pathophysiology of TMA occurring in the context of another disease/drug and have found that some harbor an underlying complement defect and some do not. Some show signs of complement activation and some do not [178]. We currently think of TMA as a spectrum disease. On one end of the spectrum, you have atypical HUS with 70% of patients harboring a genetic/autoimmune alteration resulting in complement activation and high rates of disease recurrence and progression to kidney failure. On the other end, there are forms of TMA with no evidence for complement activation and therefore in need of a different treatment, mainly treatment of the underlying condition or discontinuation of the offending drug. Most TMA occurring in the context of another disease or drugs are somewhere in between the two extremes of the spectrum, and difficult to diagnose and treat. As the TMA spectrum includes a variety of coexisting diseases triggering TMA in different ways, we suggest to not use the phrase secondary TMA but rather use a descriptive term. In a patient with TMA developed in the setting post hematopoietic stem cell transplantation, we would call it TMA associated with HSCT or transplant TMA (TA-TMA, see Table 2). We will discuss in this chapter the current evidence of TMA spectrum diseases, the role of complement activation, and treatment recommendation.

Pathophysiology and Biomarkers

There are two ways how TMA can develop in the setting of a coexisting disease and/or associated with medications:

- The patient has an underlying complement disorder/genetic susceptibility and the disease/drug triggered the onset or the recurrence of the disease [178].
- The patient has no underlying complement disorder/genetic susceptibility but the disease/drug causes endothelial cell activation that resulted in endothelial cell injury and the clinical picture of TMA. Complement activation might result in secondary due to the endothelial cell injury; short-term complement blockade might be helpful in these cases.

Some conditions, for example, pregnancy, are more commonly a trigger event and the likelihood of finding an underlying complement abnormality is high. Other conditions such as malignant hypertension and drugs are more likely to result in endothelial cell injury and secondary complement activation. Some other conditions are less well defined.

We currently do not have reliable routinely available biomarkers that can help to distinguish genetic TMA from TMA associated with co-existing diseases. Low C3 can be observed in some patients with genetically driven HUS, but is not reliable [89, 179]. Measurement of complement activation products, for example, C3d and sC5b-9 might help determine systemic complement activation. However, similar to low C3 levels, half of the patients with atypical HUS have normal levels of complement activation products [179]. This might be explained by the fact that complement activation in TMA does not take place in the fluid-phase but on the surface of endothelial cells [180, 181]. Recently, Noris et al. have developed an ex-vivo test to determine complement activation. In this assay, they add serum of patients on either activated or not-activated endothelial cells and measure C5b-9 deposition. In active disease, high C5b-9 deposition was seen on activated and non-activated endothelial cells, compared to only on activated cells during remission. This was true for samples from patients with aHUS as well as secondary TMAs. Interestingly, no C5b-9 deposition was detected in patients on eculizumab treatment [182]. Another group corroborated the results, showing massive ex-vivo C5b-9 activation in 60% of patients with TMA and coexisting diseases [183].

Table 3 lists the investigations in patients with TMA. Treatment decisions are based on clinical features and severity of the disease, and reports on complement biomarkers.

Clinical Presentation and Outcome

Clinical presentation includes microangiopathic hemolytic anemia, thrombocytopenia, and kidney disease, which can manifest as elevated creatinine, proteinuria/nephrotic syndrome or nephritis,

Table 3 Workup in patients with thrombotic microangiopathy (TMA)

Investigation	Remarks
TMA markers • Hemoglobin, leukocyte, and platelet counts; schistocytes • Hemolysis: LDH, haptoglobin, bilirubin, Coombs test • Kidney disease: creatinine, urea, urine protein	Baseline investigations; also required for monitoring
Determine underlying etiology **Infections** • Shiga-toxin: stool PCR, serology • Pneumococcal: blood, CSF culture • Infections: serology, culture (influenza, HIV, HepB/C) **Autoimmune** • Antinuclear, antiphospholipid antibodies • Antineutrophil cytoplasmic, anti-double stranded DNA antibodies **Other kidney diseases** • C3 nephritic factor; glomerular basement membrane antibodies • Kidney biopsy **In woman** • Pregnancy test **Malignancy** • Complete blood counts, blood smear **TTP** • ADAMTS13 activity assay and inhibitor **Metabolic diseases** • Plasma homocysteine, methionine; urinary methylmalonic acid • Genetics if the above tests are abnormal, and metabolic consult **Disseminated intravascular coagulation** • Prothrombin time, partial thromboplastin time, fibrinogen	Investigation tailored to patient history and presentation ADAMTS13 testing needs to be sent prior to starting plasma exchanges
Determine complement activation • C3/C4; C3d, sC5b-9 • Alternate pathway (AP50) and classic pathway (CH50) testing • FH antibodies • Genetics: *CFH*, *CFI*, *MCP*, *C3*, *CFB*, *CFHR5*, *THBD*, *DGKE;* dosage analysis for hybrid *CFH* genes; copy-number variations in *CFH* or *CFHR*	Complement studies should be done prior to plasma therapy, or eculizumab initiation CH50 used for monitoring eculizumab efficacy Take DNA specimens prior to transfusion
Other organ manifestations • Liver function, cholestasis, amylase, lipase • Electrocardiogram, echocardiography • Neurological exam; brain imaging • If severe hypertension: evaluate for end-organ damage	Investigation tailored to the patient history and presentation. TMA is a systemic disease and every organ can be involved

or hypertension. Specific algorithms were published for pregnancy-associated TMA [46] and TMA post bone marrow/hematopoetic stem cell transplantation [184]. In general, adult patients with secondary TMA when compared to adult patients with aHUS have a lower risk of requiring dialysis or developing chronic kidney disease at initial presentation but have an increased risk of death (11% vs. 2%) [185]. Death was attributed to the underlying condition rather than TMA. Neurological involvement is reported in both aHUS and TMA spectrum disorders [185, 186]. Relapse was only noted in 1 out of 110 patients [185]. The risk of developing kidney failure was high with 37% of cases and another 40% progressed to CKD stage 3–4 within

2 years [185]. Worsening of kidney function might not all be due to TMA, as other factors like chemotherapy, transplantation and other kidney diseases may have contributed. Another cohort from Korea showed a 5-year survival rate of 60% in aHUS and TMA associated with coexisting diseases, with drug-induced and patients post-HSCT transplantation having the worst survival [186].

Treatment

Why is it important to distinguish whether the underlying pathophysiology of the TMA is related to complement activation or not? Treatment differs depending on the underlying cause leading to the TMA, but also important to know whether the patient has higher susceptibility for another event in the future. Furthermore, this might be relevant for other family members who could be affected.

The terminal complement inhibitor eculizumab has tremendously improved outcome in patients with aHUS [168]. Several case reports/small case series have indicated that terminal complement inhibition might be beneficial in secondary TMA. However, there have been no controlled studies in patients with TMA spectrum disease. One recent case series describes 110 patients with secondary TMA (infections, drugs, non-renal solid organ transplantation, malignancies, other glomerular diseases, or autoimmune diseases) receiving either plasma exchange (50%) or eculizumab (38%) [185]. Eculizumab was administered in the more severe cases and in one-quarter after plasma therapy had failed. Thirteen percent showed complete remission and two-thirds showed hematological remission and improved kidney function. However, the outcome was similar to patients that were not receiving eculizumab. Treatment was well tolerated, and no major side effects were reported [185]. In a smaller case series from Spain (29 patients, mainly drug-induced TMA or TMA associated with autoimmune disease), rapid improvement of hematological and renal parameters were observed in 70% of patients, most of them having failed plasma therapy before [187]. Initiation of eculizumab was delayed in most patients, and early (<7 days) initiation in patients with aHUS has been associated with improved long-term outcome [168]. Both these series had limitations, being retrospective in nature and including a very heterogeneous group, and therefore difficult for a recommendation [185, 187]. Furthermore, some TMA have more evidence for complement activation, for example, pregnancy and transplant-associated TMA and therefore better response to complement inhibition than others. In general, treatment in TMA with coexisting diseases should include therapy of the underlying condition or removal of the offending drug, if possible. Also strict control of blood pressure to avoid further endothelial cell injury is considered beneficial. Specific disorders are discussed below.

TMA Associated with Pregnancy

Incidence and Pathophysiology

Pregnancy has long been recognized as a condition that can precipitate an episode of TMA. The two main forms of TMA – TTP and HUS – have both been linked to pregnancy. TTP – both congenital and autoimmune form – is more common in cases with TMA developing during the second or third trimester of the pregnancy [68, 188]. The development of TTP during the last two trimesters of pregnancy is believed to result from increased VWF release and subsequent ADAMTS13 activation [68]. Complement-mediated TMA developed in the majority of the cases (75–80%) in the postpartum phase and was often associated with complement defects. Genetic screening of women with pregnancy-associated TMA showed an underlying genetic abnormality in 80% of the cases [188]. Additionally, patients had similar clinical presentation, rates of extra-renal complications and outcome, when compared to female patients with atypical HUS not related to pregnancy [189–191]. Pregnancy and nonpregnancy-related TMA share common genetic risk factors with a similar frequency (86% vs. 74%) and also share the same type of AP dysregulation, the most frequent abnormality being CFH mutations (40%) [189–191]. Pregnancy complications were common in women with pregnancy-associated TMA:

55% had pre-eclampsia and 33% HELLP syndrome [190]. Pregnancy TMA is considered to be mainly complement mediated.

Clinical Presentation and Diagnostic Approach

Clinical presentation is similar to other TMAs. Dialysis was required in 70% of patients. Diagnosis in patients with pregnancy-associated TMA is often delayed, due to the significant clinical overlap with HELLP syndrome and preeclampsia [190]. A recent consensus paper [46] suggested the following criteria to diagnose TMA in pregnancy:

- Platelet count $<100 \times 10^9$/L
- Hemoglobin level <10 g/dL
- LDH >1.5 upper limit of normal
- Undetectable serum haptoglobin
- Negative direct erythrocyte antiglobulin test
- Schistocytes on a blood smear (1), or features of TMA on kidney biopsy (2)

One should also consider the differential diagnoses and rule out HELLP syndrome and other possible underlying diseases such as SLE or catastrophic antiphospholipid syndrome (CAPS). An algorithm was published in the recent consensus paper [46]. Every patient should have an ADAMTS13 function and antibody test to rule out TTP. If this is negative a diagnosis of complement-mediated TMA can be made, treatment can be initiated and further workup is warranted [46, 82]. This workup includes genetics, autoantibodies, and complement activation markers as outlined in Ref. [68] (Table 3).

Treatment and Outcome

Outcome in patients with pregnancy-associated TMA is characterized – similar to aHUS – by high rates of kidney failure and disease recurrence [188, 190, 191]. ESKD was described in 50% over 7 years, with an additional 20% having reduced kidney function [189]. Relapses were observed in one-fourth of the patients. As pregnancy TMA has long been perceived as a complement-mediated disease several women were treated with eculizumab, which has significantly reduced rates of kidney failure [190, 191]. Eculizumab has been considered to be safe to use during pregnancy [190–194]. Plasma therapy was used in some patients with minimal response [188, 191]. Plasma exchange is the hallmark therapy for patients with pregnancy-associated TTP and often PLEX is started while ADAMTS13 testing is pending. Once ADAMTS13 is negative and other differential diagnoses have been excluded, patients should be commenced on anti-complement treatment. Treatment duration suggested by the recent consensus paper is a minimum of 6 months. If creatinine has been stable for >3 months, it can be considered to stop complement blockade [46].

Special Considerations

1. Women with aHUS can get pregnant but should be followed closely until 3–4 months post-delivery. The risk of recurrence during pregnancy is estimated as 20–25% [190, 193]. In the case of relapse during pregnancy prompt anti-complement therapy should be initiated to increase the chance of renal recovery and term live birth [46].
2. The miscarriage rate in patients with pregnancy-associated TMA is 9–14% (similar to the general population); however, one-third of babies show low birth weight [193, 194].
3. Patients who wish to get pregnant after a previous episode of pregnancy-associated TMA require counseling and close monitoring, as they have a high chance of relapse. Prophylactic anti-complement blockade may be considered in specific cases [193].

TMA Associated with Solid Organ Transplantation

Incidence and Pathophysiology

TMA post kidney transplantation can occur as a recurrence of aHUS or de-novo. TMA has also been described in patients post lung, heart, liver, intestinal, and pancreas transplantation [195]. TMA post solid organ transplantation is rare. In a recent meta-analysis, an incidence of 2–4% was reported in non-renal solid organ transplant patients and 1–14% in renal transplant recipients, with some TMA only evident in biopsies without hematological features [196]. The mechanism of endothelial cell dysfunction resulting in TMA post solid organ transplantation is thought to be multifactorial, including the use of cyclosporine and/or tacrolimus (calcineurin inhibitor, CNI) or other immunosuppressive drugs, infections, alloimmune reactions, rejection, and ischemia-reperfusion injury [197]. CNI is frequently used as part of the immunosuppressive regimen post transplant, and numerous reports describe the recovery of TMA with cessation of the drug. The first pediatric case of CNI-associated TMA was reported in 1999. Changing from cyclosporine to tacrolimus appeared to lead to renal recovery [198]. CNIs result in renal arteriolar vasoconstriction and increased platelet aggregation [197, 199]. In an attempt to limit the risk of calcineurin-inhibitor-associated nephrotoxicity, the use of the mTOR inhibitors sirolimus and everolimus have been proposed, however, de-novo TMA were also observed in patients with mTOR inhibitors [200]. In addition to blocking cell cycle progression and proliferation, mTOR inhibition also leads to decreased renal expression of vascular endothelial growth factor (VEGF) and death of endothelial progenitor cells; these latter anti-angiogenic effects are believed to contribute to the pathogenesis of TMA [201, 202]. Highest rates of TMA have been reported in patients on a combination of mTOR inhibitor and CNI [203]. Genetic studies revealed that 30% of patients with de-novo TMA post kidney transplantation harbor genetic variants in complement genes. This implicates a role for complement dysregulation, and surgery, infections, and immunosuppressive drugs could represent triggers that result in the manifestation of TMA in patients with genetic susceptibility [176]. The role of complement is less defined in non-kidney solid organ transplantation.

Clinical Presentation and Diagnostic Approach

There are no diagnostic criteria for TMA post solid-organ transplantation. In kidney allograft recipients, TMA can be restricted to the native kidneys, to the graft, or manifest systemically [195]. Thrombocytopenia and Coombs negative anemia are the main hematological symptoms, which can be difficult to interpret in liver transplants. Impaired renal function or failure is present in most cases; a biopsy is helpful to confirm the diagnosis [204]. One also needs to consider whether there is a chance that the patient's primary disease was aHUS and this is a recurrence rather than de-novo TMA. Antibody-mediated rejection (ABMR) results in endothelial cell injury and TMA can be a presenting feature [204]. TMA in ABMR has been associated with worse outcomes [205]. TMA post solid-organ transplantation, especially after kidney transplantation, warrants further workup as detailed in Table 3. A kidney biopsy is recommended, mainly to diagnose antibody-mediated rejection or other de-novo glomerulonephritis, such as lupus nephritis.

Treatment and Outcome

Prior to the use of complement inhibitors, systemic de-novo TMA was associated with poor outcome in adults: 40% graft loss rate and 50% mortality rate [200]. Similarly, TMA recurrence in the allograft was associated with high graft loss rates, but has much improved since using complement inhibition [177, 206]. Treatment of post-transplant de-novo TMA is often implemented in a stepwise fashion depending on what is believed the most likely etiology [204]. The first step has often been to discontinue or switch immunosuppressive drugs and that has frequently been shown to improve hematological parameters [204]. However, this has to be a careful consideration as decrease in immunosuppression might put patients at risk for rejection. Also, temporary or permanent discontinuation of CNI after the development of de novo TMA in the allograft has not been consistently shown to improve long-term graft outcomes [205]. Improved outcomes have been reported with PLEX and IVIG therapy in TMA associated with ABMR presumably as a result of the removal of HLA antibodies [205]. Similarly, to aHUS, several case reports show improved graft outcomes if patients were treated with CNI withdrawal and PLEX [207]. Recently, several case reports report the successful use of complement inhibition in patients with de-novo TMA post kidney and non-kidney transplantation [204, 208]. Of note, there are also some patients with ABMR with and without TMA that showed response to eculizumab [204]. There is no current recommendation on treatment, however, with previous reports showing that 30% have complement alterations we feel that complement inhibition should be promptly started in patients with systemic or biopsy-proven TMA and impaired kidney function, patients with a family history of TMA or unknown cause of kidney failure, as well as patients were switching immunosuppression or discontinuation is not feasible. In centers without access to complement targeted therapy, PLEX should be considered as an option.

TMA Associated with Hematopoietic Stem Cell Transplantation

Incidence and Pathophysiology

TMA associated with hematopoietic stem cell transplantation (HSCT) is recognized as a severe complication and significantly affects patients' well-being and transplantation outcome. It is mainly reported after allogeneic HSCT, but can also occur after autologous transplantation [209]. TMA was reported in 10–30% of pediatric patients post-HSCT, with one-third of them having severe disease [184]. TMA develops in the majority of patients within 100 days post transplant in median after 3 weeks [184]. Untreated patients with severe TMA (see criteria below) had a 1 year's survival of 17% and overall survival of 9%, milder cases had a risk of developing CKD [210]. Survival has much improved since complement target therapies became a cornerstone of treatment in severe cases. However, there remain challenges in diagnosing these patients and long-term renal involvement is common. Pathophysiology of TMA in patients post HSCT includes endothelial cell injury that results in a procoagulant state, activation of antigen-presenting cells, and activation of the complement system [211]. Risk factors include medications such as conditioning treatment and immunosuppression with calcineurin inhibitors, mTOR inhibitors, and infections [209]. A majority of patients with severe TMA (80%) show elevated markers of alternative and terminal complement activation [184], some even harbor variants of unknown significance or a homozygous *CFHR1/3* deletion [212].

Clinical Presentation and Diagnostic Approach

Hematological parameters are often not useful in patients post-HSCT and markers of kidney impairment, for example, hypertension and proteinuria, become important. Screening for TMA should therefore include regular CBC, blood smear, LDH, kidney function, urine dipstick, and blood pressure measurements. Nephrotic range proteinuria is described in half of the patients, 25% of patients required dialysis. Extrarenal complications are common, for example, pulmonary hypertension in 17%, severe pericardial effusion requiring drainage in 19%, lower GI bleeding in 35%, neurological symptoms in 33%, and occasionally multi-organ dysfunction syndrome. High-risk TMA according to the Cinicannti group is diagnosed if one of the following three conditions is present:

- TMA confirmed on kidney biopsy (A), OR
- Clinical diagnosis of TMA (5 out of 7 markers must be present and must include 6 and 7, B):
  1. LDH above normal for age
  2. Schistocytes on blood smear
  3. De novo thrombocytopenia or increased transfusion requirements
  4. De novo anemia or increased transfusion requirements
  5. Hypertension >99% for age (<18 years) or >140/90 mmHg (18 years of age)
  6. Proteinuria 30 mg/dL × 2; random urine protein/creatinine ratio >2 mg/mg
  7. Terminal complement activation (elevated plasma sC5b-9 above normal)

  Multi-organ dysfunction syndrome (at least 1 organ, C) and the presence of 5 of 7 criteria with at least one high-risk marker present (either 6 or 7 from criteria B).

A kidney biopsy is helpful in making the diagnosis, but often not feasible and then diagnosis is made on clinical basis using the above criteria. The workup is outlined in Table 3.

Treatment and Outcome

Eculizumab is considered the first-line treatment for patients with high-risk TMA post HSCT. Treatment differs from patients with aHUS as patients with TMA post-HSCT need more frequent dosing initially (sometimes as often as every 48 h) and can then be commenced on a rapid taper. Treatment monitoring using CH50 or eculizumab levels, if available, should be done regularly to assure the patient has adequate terminal complement blockade. If complement monitoring is not readily available, one has to closely monitor TMA markers (daily) and in patients with blood loss and frequent transfusions decreasing the interval between infusions should be considered in patients with inadequate response.

A meta-analysis of 116 patients from six studies indicated an overall response rate of 71%, complete remission in 32%, and survival in 52% [213]. A more recent report by the Cincinnati group shows a response rate of 64% and a survival rate of 66% 1-year post high-risk TMA [184]. The improved outcomes are most likely attributed to early initiation and efficient complement blockade in the first 2 weeks after diagnosis by dosing eculizumab to achieve trough levels ≥ 100 μg/mL and CH50 $<10\%$. Prognostic factors included a high pre-therapy sC5b-9 which was associated with a lower response rate, worse outcomes, and requiring more doses of eculizumab, reflecting massive complement activation and severity of the disease [184]. Patients with intestinal bleeding did worse. They also had higher eculizumab clearance and needed more doses, and a worse outcome. Even though patient survival has much improved, over 70% still have chronic kidney disease with lower GFR and persistent proteinuria [184]. Treatment of mild disease includes management of hypertension and decrease of immunosuppressive therapy, and treatment of infections.

TMA Associated with Autoimmune Diseases

TMA – HUS and TTP – seems to be overrepresented in systemic autoimmune diseases [214]. Systemic lupus erythematosus (SLE) and other connective tissue diseases are the most common diseases; however, others have been reported (Table 2) [178, 214]. TMA has also been described in patients with inflammatory bowel disease [215]. In the majority of cases, TMA occurs either concurrently with underlying autoimmune disease or after [214]. The difficulty is to diagnose TMA as clinical symptoms overlap significantly and biopsy is usually key to making the diagnosis. Treatment is mainly guided by the underlying disease, however, in refractory cases, PLEX and complement inhibition have been successfully attempted [216].

Systemic Lupus Erythematosus

Incidence and Pathophysiology

The prevalence of TMA in SLE patients is estimated at 1–9% with a higher prevalence in patients with lupus nephritis [216, 217]. TMA lesions in renal biopsies of patients with SLE were detected in a higher proportion (24%), however, most of them were lacking the clinical diagnosis of TMA [218]. TMA in majority occurs at the time of lupus onset or in a patient with known SLE [214]. Triggering factors include infection, pregnancy, lupus flare, and non-adherence [216]. In SLE, the formation of immune complexes activates the classical pathway and results in subsequent tissue inflammation [219]. Activation markers of alternate, classic, and terminal pathways were associated with disease activity in pediatric patients [220]. Complement defects are rare, but they are associated with increased risk for SLE [219]. In a large case-control study with 15,864 patients with SLE, the deletion of *CFHR3* and *CFHR1* was linked to the development of SLE [221] and in a different study, 6.7% of SLE patients had FH antibodies [222]. The pathogenesis of SLE-associated TMA remains unknown.

Clinical Presentation and Diagnostic Approach

Clinical symptoms for TMA in patients with SLE include thrombocytopenia as well as microangiopathic hemolytic anemia (DAT negative) with schistocytes and kidney disease. TMA should be suspected in SLE patients with rapidly progressive or persistent kidney disease (AKI, proteinuria, hematuria) and hypertension [216, 217]. Some adult case series report a 30–50% rate of dialysis in the acute phase [216, 217]. Of note, TMA should be suspected in patients on immunosuppressive therapy. Pathological evidence is key to identifying patients. Kidney biopsy commonly shows glomerular and vascular TMA including evidence of endothelial swelling, capillary and artery wall thickening, luminal fibrin thrombi, and erythrocyte fragmentation [214, 217].

Treatment and Outcome

Treatment of TMA in patients with SLE is most often guided by the treatment of the primary disease. Additionally, tight control of hypertension should be achieved to prevent further endothelial cell injury. Plasma exchange and complement inhibition with eculizumab has been reported as beneficial in some patients. Two retrospective analyses of 56 and 16 patients treated with PLEX indicate its benefit if administered seven or more times [217, 223]. There are several published cases that indicate the successful use of eculizumab, others show no difference in renal outcome (reviewed in Ref. [216]). One case report presents the successful use of intravenous soluble thrombomodulin [224]. In adults, the renal outcome is worse in patients with TMA [216, 225].

Antiphospholipid Syndrome (APS)

APS or life-threatening catastrophic APS (CAPS) is an autoimmune disease characterized by arterial and venous thrombi due to autoantibodies directed against phospholipids [226]. Kidney involvement (APS nephropathy, APSN) is common (71% during the course of disease), histopathologically often reflected by TMA [227]. APS is associated with recurrence post-transplant, especially presenting as TMA in the early phase after renal transplantation. Antiphospholipid antibodies lead to complement activation, likely via the classical pathway but increased C5a levels were also described [228, 229]. There have been case reports of patients with APS and TMA in biopsy (native and transplant kidneys) which were treated with eculizumab after failing PLEX treatment. Complement inhibition resulted in reversing clinical and histopathological findings of TMA [228].

Antineutrophil Cytoplasmic Antibodies (ANCA) Associated Vasculitis

TMA was detected in 10–15% of patients with ANCA-associated vasculitis [230]. TMA in these patients was associated with worse kidney disease and overall mortality [230]. Endothelial cell activation and injury in vasculitis are induced by activated neutrophils. This ANCA mediated response is amplified by alternate pathway activation on the endothelium, initiated by properdin and factor B released from activated neutrophils resulting in enhanced C5a production, closing an amplification loop of neutrophil activation [231]. Animal studies suggest a therapeutic role of anti-C5 blockade and clinical trials with avacopan, a small molecule antagonist of the human C5aR are promising [232]. The successful use of eculizumab was also described in a case report of ANCA-associated vasculitis [233].

TMA Associated with Cobalamin C Deficiency

Cobalamin C deficiency-associated HUS is a rare form of TMA and has been reported in fewer than 150 cases [89, 104, 110]. Inheritance is autosomal recessive and patients carry a mutation in the MMACHC (methylmalonic aciduria and homocystinuria type C protein) gene. TMA associated with Cobalamin C deficiency typically presents in the neonatal period with vomiting, poor sucking, failure to thrive, lethargy, hypotonia, thrombocytopenia, microangiopathic hemolytic anemia, and renal injury [234, 235]. Common renal involvement includes proteinuria, hematuria, and acute kidney injury including the need for short-term dialysis [127]. Case reports have also described the presentation of TMA in older children. Adult onset is extremely uncommon but reported [236].

Regardless of age at presentation, neurologic symptoms are prominent and also include cognitive impairment, ataxia, and psychosis.

Suggested mechanisms for TMA include endothelial damage induced by hyperhomocysteinemia, impairment of the nitric oxide-dependent inhibition of platelet aggregation, or induction of a procoagulant state of the endothelium leading to the formation of microthrombi [127]. Of note, a TMA-like picture has also been reported in patients with acquired cobalamin C deficiency [237].

A direct result of the cobalamin metabolism abnormalities, the biological hallmarks of Cbl C disease are hyperhomocysteinemia, low blood methionine, and methylmalonic aciduria. A finding of these laboratory abnormalities, particularly when no other diseases associated with TMA are identified, is enough to trigger a trial of therapy. Parenteral hydroxocobalamin combined with oral folinic acid and betaine is the recommended treatment for Cbl C disease [133].

The effectiveness of treatment regimens for patients with Cbl C disorder with or without TMA is variable. High mortality has been reported for infantile Cbl C-associated HUS [127, 131]. Improvements in biochemical, hematological, and growth parameters have been consistently reported in response to the treatment. Unfortunately, developmental delay, neurological involvement, and persistence or worsening of visual complications may persist. End-stage kidney disease is generally prevented by treatment.

TMA Associated with Drug Exposure

TMA from drug exposure may occur either from a toxin-mediated effect (dose-dependent or dose-independent) or it may occur from a dose-related, immunologic reaction. There are no reliable distinguishing features between drug-induced TMA and any of the other causes of TMA. Often the mechanism of disease pathology is not clearly defined. Renal failure is often present and ranges from mild to severe. Evidence supporting a direct causal role is limited for most reported associations. In a recent meta-analysis of the literature 78 drugs were described, however, the authors suggest that only 22 drugs had evidence supporting a causal relation to the TMA [238], the list is detailed in Table 2. Among the most reported agents that have been implicated include chemotherapeutic agents (gemcitabine, mitomycin, and cisplatin), calcineurin inhibitors (cyclosporine, tacrolimus), tyrosine kinase inhibitors, and vascular endothelial growth factor inhibitors [238–240]. Historically both ticlopidine and clopidogrel have also been associated with TMA but are infrequently used in the pediatric setting [241]. Quinine exposure is well reported to cause TMA in susceptible individuals [242, 243].

In general, treatment of TMA associated with drugs is guided by withdrawal of the potentially offending agents and monitoring for recovery. Plasma therapy has had unreliable effects and also the use of anti-complement therapy has been with mixed results [185, 187].

Quinine

Quinine exposure in children is highly unusual; however, it is worth mentioning quinine as the prototypical immune-mediated drug related to TMA. Initially recognized as recurrent kidney injury associated with hemolysis and thrombocytopenia after repeated quinine exposures [243], the mechanism for quinine-induced HUS is now reasonably well-defined. Antibody binding to multiple cells is facilitated by the presence of quinine – triggering disease [242, 244]. Quinine-dependent antibody binding may mediate thrombotic microangiopathy. Quinine-induced TMA often presents with sudden onset anuric renal failure. Few other systems are involved. In adults, supportive treatment including dialysis is often required. There is no evidence to support immune suppression or plasma therapy. Chronic kidney disease with hypertension is common in follow-up, and end-stage kidney disease is reported [245].

Chemotherapy

TMA occurring after exposure to chemotherapeutic agents is reported in both children and adults [238, 246]. Presentation includes not only the classic hematologic triad but also significant hypertension and renal failure. Extrarenal findings are much less common than in the other forms of TMA. Dose dependency was described for some drugs [247].

TMA following *mitomycin* exposure may be severe and lead to end-stage renal disease [248]. It often occurs 4–8 weeks after the last dose and after a cumulative dose of 40–60 mg. Mortality was reported to be as high as 70% [240]. Multiple cases of gemcitabine-associated HUS have been reported in adults [249]. Its incidence has been reported to range from 0.15% to 4% after treatment for 6–8 months with a total dose of 22.5 (±14) mg/dL. Kidney failure, hypertension, and proteinuria are common features [240]. Kidney biopsies have shown C3 deposition and successful use of eculizumab was described, indicating there might be a role for complement activation in its pathophysiology [250]. Cisplatin, an agent used for childhood tumors, has been reported in association with TMA [251]. Limited evidence suggests that cisplatin not only causes widespread endothelial damage but also may precipitate glomerular basement membrane and podocyte damage [252].

Additional chemotherapeutic agents that were reported to trigger TMA: bleomycin, doxorubicin, 5-fluorouracil, carboplatin, daunorubicin, dacarbazine, oxaliplatin, lomustine, vinblastine, tamoxifen, carmustine, tretinoin, and cytarabine [238]. Because TMA is also reported with cancer and independent of chemotherapeutic agents, ascribing the cause is difficult [240].

VEGF Inhibitors

Vascular endothelial growth factor (VEGF) inhibitors are the latest in chemotherapy agents with an association with TMA (sunitinib and bevacizumab) [239, 253, 254]. VEGF is produced by the podocytes and travels retrograde up the glomerular filter to maintain healthy endothelial cells. Lack of VEGF will result in changes of vascular tone, for example, vasoconstriction, which is also the proposed mechanism for hypertension induced by anti-VEGF therapy and often a leading symptom together with non-nephrotic range proteinuria [254]. For bevacizumab, the incidence of hypertension is reported as 25% and the incidence of proteinuria as high as 21–62% [239]. Biopsy often shows the hallmark features of TMA, including widening of the subendothelial spaces of glomerular capillaries, double contour of the GBM, mesangiolysis, effacement of foot processes, and endothelial swelling with overt thrombosis [254]. There have been some reports of worsening hypertension, proteinuria, and TMA even after intravitreal use of VEGF inhibitors, however, much less common compared to systemic use [255]. All patients receiving systemic anti-VEGF require close monitoring of their blood pressure and regular urine assessment for proteinuria. Improvement of proteinuria and hypertension was reported after the drug was discontinued [254].

TMA Associated with Infection

Besides STEC HUS, TMA has been reported to occur in the setting of several different bacterial, fungal, and viral infections. For a full list please see Table 2 (reviewed in Ref. [178], updated for Covid-19 infection [256] and fungal infection [257]). Besides EHEC- and Shigella-associated HUS in the developing world, pneumococcal HUS is the most frequent form of postinfectious HUS, accounting for around 5% of all childhood-onset HUS [258]. Atypical HUS onset or relapse is often triggered by even a simple infection or cold. If a TMA occurs in the setting of an infection, one has to ask themselves whether the infection could be a trigger and workup as shown in Table 3 should be performed.

If there are concerns for complement-mediated TMA (positive family history, recurrent disease, low C3, severe disease), one might consider treatment as in aHUS until work-up is back. In mild disease, one can treat the infection and monitor for resolution of symptoms of the TMA. It is more difficult to make this decision in severe infections. Additionally, sepsis is known to cause complement activation, including terminal pathway, and causes endothelial cell injury [259, 260]. TMA in septicemia and endocarditis [261] has also been described. However, before initiation of terminal complement inhibition one has to weigh the pros and cons, due to the risk of pneumococcal and meningococcal infections [262]. In a large pediatric cohort post hematopoietic stem cell transplantation, no increased rate of infections was seen in patients receiving eculizumab for TMA. Several bacterial, viral, and fungal infections were documented but none of them resulted in death. Of note, all patients received antibiotic prophylaxis while on eculizumab [184].

Streptococcus pneumoniae HUS

HUS may occur following an invasive infection with *Streptococcus pneumoniae*. With the emergence of the pneumococcal vaccine, the overall incidence of pneumococcal HUS has been decreasing in North America in recent years. The most common serotypes also changed over time, although serotype 19A – although covered in the 13 valent pneumococcal vaccine – is still the most common serotype [263]. The preceding *Streptococcus pneumoniae* infection is usually severe and invasive, and children may present with septicemia, meningitis, and/or pneumonia with empyema [3, 202, 205]. Children with pneumococcal HUS were generally younger, had more severe renal and hematological disease, and were more likely to require dialysis compared to patients with STEC HUS [264]. Patients with pneumococcal HUS also had a higher incidence of cortical necrosis and long-term renal and extrarenal complications compared to STEC HUS [264–266].

S. pneumoniae produces neuraminidase, which cleaves N-acetyl neuraminic acid from cell surfaces and thereby exposes the Thomsen–Friedenreich antigen (T-antigen) on cell surfaces. Naturally occurring antibodies bind the T-antigen leading to hemolysis (Coombs test positive), thrombosis and endothelial damage, and the clinical picture of TMA [91]. A similar mechanism was proposed for other neuraminidase-producing microbes such as influenza A [94]. *S. pneumoniae* activates the classical pathway, and early complement proteins (of all three pathways) are required for *S. pneumoniae* killing. Studies that looked into underlying complement defects found a higher amount of rare genetic variants in pneumococcal HUS patients, including the aHUS-risk polymorphisms in the *CFH-CFHR3-CFHR1* region [267, 268]. Based on these findings, we recommend complement genetic screening in patients who develop HUS in the context of *S. pneumoniae* infections, as well as to analyze aHUS-risk variants in these patients. Further research also points toward desialylated FH having a lower capacity to regulate complement activation on cellular surfaces [267].

Treatment focuses on treating the underlying infection. There have been case reports describing the use of eculizumab, especially in patients who showed signs of complement activation [269]. With the small number of published cases, it is difficult to give treatment recommendations.

TMA Associated with Malignant Hypertension

The link between malignant hypertension, nowadays mainly defined as a hypertensive emergency, and aHUS is the subject of an ongoing debate. Is the TMA complicating malignant hypertension due to an underlying complement defect or secondary to severe hypertension and secondary endothelial cell injury. Hypertensive emergencies complicated an aHUS diagnosis in 50% of adult patients [68]. Further 50% of those harbor underlying pathogenic variants, which is similar to patients with TMA not associated with severe hypertension. Their outcome was also comparable [68]. On the other hand, patients with malignant hypertension have only a small risk of developing TMA (3%) [270]. Indicators for the hypertension being more likely essential and not related to TMA are male, >45 years, previous history of hypertension, no clots on kidney biopsy, no need for renal replacement therapy, and quick recovery (<72 h) of the TMA with strict blood pressure control [68]. Clues that favor atypical HUS diagnosis are positive family history and recurring/persistent episodes of hematological features of TMA. Of note, some patients with malignant hypertension associated with TMA did not present with thrombocytopenia in the first place and diagnosis of TMA was only made by kidney biopsy [271]. A recent report of 26 Caucasian patients, with hypertensive emergency, and TMA confirmed by kidney biopsy, showed that patients presented with severe disease (neurological manifestations in 23% and dialysis in 65%) but profound systemic hemolysis was absent in 73%. Rare complement gene variants were present in 8 patients (31%). Sera from 17 of the 25 patients who were tested induced increased deposition of C5b-9 on endothelial cells in an in vitro assay compared with pooled normal human sera, regardless of the presence or absence of complement gene variants. Sixty-one percent of patients progressed to kidney failure within 3 months of diagnosis, five of seven patients responded at least partial response to eculizumab [271]. In pediatrics, TMA due to malignant hypertension is rare and a patient presenting with TMA and a hypertensive emergency should be considered for a patient with aHUS, and diagnostics as outlined in Table 3 should be sent. It is reasonable to start this patient on anti-complement therapy, especially if no rapid recovery after initiation of anti-hypertensive drugs is noted.

Conclusion

STEC HUS (▶ Chap. 24, "Infection-Related Hemolytic Uremic Syndrome (HUS)") and TTP (above) are defined by specific pathomechanisms – STEC HUS by Stx-producing *E. coli*, and TTP by the appearance of ULVWF multimers due to genetic or autoimmune defects in ADAMTS13. Different from these, aHUS and the spectrum of secondary TMAs are caused by injury to the vascular endothelium caused by complement dysregulation due to mutations or autoantibodies in primary aHUS, or enhancing endothelial lesions caused by a spectrum of underlying pathologies in secondary TMA [272]. Of note, both forms often follow preceding triggers [178]. A systematic and standardized approach to the diagnostic work-up of TMA patients is required to determine the correct diagnosis and, thus, identify the patients in whom the use of complement modulating medications is indicated. The documented treatment benefit of complement blockers in aHUS patients [168] holds major promise for future advancements in the outcomes and the quality of life of TMA patients.

Abstract

Hemolytic uremic syndrome (HUS) is a thrombotic microangiopathy (TMA) clinically defined by thrombocytopenia, nonimmune microangiopathic hemolytic anemia, and acute kidney injury. HUS is categorized as infection-related HUS, typically caused by Shiga toxin producing *Escherichia coli* (STEC), rarely by *Streptococcus pneumoniae*, as atypical HUS (aHUS), or as secondary HUS with a coexisting systemic disease. Recent data indicated the involvement of the complement system in the pathogenesis of infectious agent-induced HUS as well. This chapter reviews current concepts of infection-related HUS in the point of view regarding the classification, epidemiological findings, pathophysiological and clinical aspects of STEC, *Streptococcus pneumoniae*, and other infectious agent-associated HUS, and their diagnosis and management.

Keywords

Acute kidney injury · Hemolytic anemia · Thrombocytopenia · Thrombotic microangiopathy · *Escherichia coli* · STEC-HUS · *Streptococcus pneumoniae* · Pneumococcal HUS · aHUS · Complement system

Introduction and Classification

Thrombotic microangiopathies (TMA) is a heterogenous group of diseases where central pathophysiological principle is development of miniscule thrombi in microvasculature of organs including glomeruli. This is usually preceded by endothelial injury by various means. Though the final manifestation of TMA is similar, the etiology and pathophysiology are vastly different and have implications for management [1].

The greatest deal of cases is secondary to infections where the Shiga toxin producing *Escherichia coli* (STEC) is the most common. Hemolytic uremic syndrome (HUS) secondary to other infections is rare in comparison. The following classification summarizes infectious related causes of HUS (Table 1).

Epidemiology

Incidence of STEC Infection and STEC-HUS

HUS is characterized by the triad of hemolytic anemia, consumptive thrombocytopenia, and acute kidney injury. In children, STEC is the leading cause of HUS and accounts for approximately 90% of cases in Europe [2, 3] and 65% in Japan [4]. In 1983, *Escherichia coli* O157:H7 were detected in the stool of patients in an outbreak of hemorrhagic colitis associated with undercooked beef patty consumption [5], and Shiga toxin (Stx) was identified in the stool from the patients with HUS in the same year [6]. The incidence of STEC infection and a combination of STEC-HUS has been analyzed epidemiologically in various countries around the world. According to a global analysis based on articles and database

Table 1 Classification of infection-associated HUS

A. STEC caused HUS
B. *Streptococcus pneumoniae*-associated HUS
C. Other infectious agent-associated HUS Shigella Viral infection – influenza [1]

from 21 countries, the incidence of STEC infection has been estimated to be 43.1 cases per person-year from 1990 to 2012 [7]. This analysis estimated that 3,890 of 2,801,000 cases with STEC infection developed HUS annually. The age-specific incidence of STEC infection and STEC-HUS were estimated respectively as 28.8% (n = 809,000) and 41.9% (n = 1,630) in patients aged 0 to 4 years, 19.8% (n = 554,000) and 18.5% (n = 720) in patients aged 5 to 15 years, 34.8% (n = 974,000) and 26.0% (n = 1,010) in patients aged 16 to 59 years, and 16.6% (n = 464,000) and 13.6% (n = 530) in patients aged over 60 years [7]. These results suggested that both STEC infection and combined STEC-HUS occur more frequently in younger children than any other age group.

In the United States, the incidence of STEC infection increased gradually in 2015 to 1.5 cases/100,000 person-year from the beginning of 2000, and the incidence of STEC infection in children aged 1 to 4 years was the highest of all age groups for both O157 and non-O157 serogroups [8]. In the European Union, the incidence of STEC infection was reported to be 1.7 cases/100,000 person-year with children of ages 1 to 4 years having the highest incidence of 6.0 cases per 100,000 person-year among all age groups, followed by children aged below 1 year having 4.5 cases/100,000 person-year [9] (Table 2). In Japan, STEC infection is a notifiable disease, and its incidence including asymptomatic carrier is reported to be 2.7–3.5 cases/100,000 person-year since 2006 [10]. In 2019, 3,744 cases with STEC infection including 1,223 asymptomatic carriers were reported, with the highest incidence being in children aged 0–4 years, followed by those aged 5–9 years [11]. Therefore, it is clear from the epidemiological data from these countries that STEC infection is mainly contracted by the young children.

In Japan in 2019, 78 cases (3.1% of symptomatic patients with STEC infection) of the 3,744 cases of STEC infection developed STEC-HUS. The incidence of STEC-HUS among the symptomatic patients with STEC infection was the highest at 0–4 years of age (6.0%), followed by 5–9 years (5.9%), and 10–14 years (4.5%), indicating that the proportion of STEC-HUS patients among symptomatic STEC patients was higher in the younger age groups [11]. In the European Union, 8–12% of patients with STEC infection is reported to develop to HUS [9], among which the data from 2015 in France estimated the incidence rate of STEC-HUS to be 0.94 cases/100,000 person-year in children younger than 15 years of age. The estimated incidence of STEC-HUS in children aged less than <3 years (3.1 cases/100,000 person-year) was higher than those in children aged 11–14 years (0.2 cases/100,000 person-year) [12]. The epidemiological data of these countries confirmed the higher incidence of both STEC infection and STEC-HUS in

Table 2 Notification rates of confirmed STEC infection by age group and sex in the United States and EU/EEA

Age	United States in 2015 (Ref. [8])				EU/EEA in 2010–2012 (Ref. [9])		Age

younger children, and it occurs more commonly in summer months.

Incidence of *Streptococcus pneumoniae*-Associated HUS

The *Streptococcus pneumoniae*-associated HUS (P-HUS) is reported to account for 4–5% of total HUS, and its annual incidence is estimated to be 0.015 to 0.06 per 100,000 children [2, 13, 14]. In addition, it has been reported that complicated pneumonia is strongly associated with P-HUS among various symptoms of invasive pneumococcal disease (IPD) including septicemia, meningitis, and complicated pneumonia. Although the incidence of IPD has decreased after the introduction of seven-valent pneumococcal conjugate vaccine (PCV7) [15], the incidence of P-HUS has increased rather than decreased [13], and the incidence of P-HUS among IPD patients has also increased [14]. A 19A serotype, not included in PCV7, has been frequently reported as a pneumococcal serotype identified as the cause of P-HUS. Since the 19A serotype is included in the 13-valent pneumococcal conjugate vaccine (PCV13), it is necessary to analyze whether PCV13 allows for a decreased incidence of P-HUS.

STEC-Associated HUS

Pathogenesis and Pathophysiology

Microbiology of *Escherichia coli*

The most common STEC serotype identified in cases of hemorrhagic enterocolitis and HUS in the United States, the European Union, and Japan is O157:H7. However, various serotypes of STEC have been identified to date. Non-O157 serotypes, such as the 2011 German O104:H4 outbreak and the O111 outbreak in Japan, can also cause an outbreak of hemorrhagic colitis and HUS. The 2011 German outbreak affected all age groups but predominantly females aged around 35 years and was identified as a multiresistant EAEC strain disseminated by contaminated sprouts [16]. This finding also challenges the concept of Gb3 surface expression as the only pathomechanism in STEC-HUS.

Recently, it has been reported that the ratio of O157 serogroups and of non-O157 serogroups has changed in STEC infections. In the United States, between 2000 and 2010, the incidence of O157 STEC infection decreased from 2.17 cases/100,000 person-year, and the incidence of non-O157 STEC infection increased from 0.12 cases/100,000 person/year, with both incidences reaching equivalent value of 0.95 cases/100,000 person-year [8]. In 2015, the incidence of O157 STEC infection and non-O157 STEC infection were 0.66 and 0.84 cases/100,000 person-year, respectively, and the incidence of non-O157 STEC infection exceeded the incidence of O157 infection [8] (Fig. 1). In the European Union, although O157 is the most common serotype in STEC infection and its rate was stable, it accounted for only 55% of the identified cases from 2007 to 2012 [9, 17] (Fig. 2). In Japan in 2019, the O157 serotype accounted for 54% of the identified cases [11]. The proportion of O157 serotype in STEC infection has tend to decrease in both countries having implications for diagnosis. The non-O157 strains are usually not detected by classical microbiological methods and require utilization of STEC PCR diagnostic [18].

Source of Infection

Cattle and its intestine are considered the primary reservoir of STEC. Deer, sheep, goats, horses, dogs, flies, and humans can also become vectors of STEC infection. Undercooked meat, contaminated by feces in abattoir, are common source of STEC infection. Feces-contaminated fruit and vegetables including fenugreek sprouts, unpasteurized dairy products, and contaminated water [19, 20] can become vehicles for transmission of STEC and were found as mean of infection in major outbreaks. In addition, petting zoos and close contact with farm animals have been identified as a source of STEC infections [19]. A meta-analysis of sporadic cases suggested the significance of ingestion of undercooked meat, contact with animals, and exposure in environments with feces of the animals

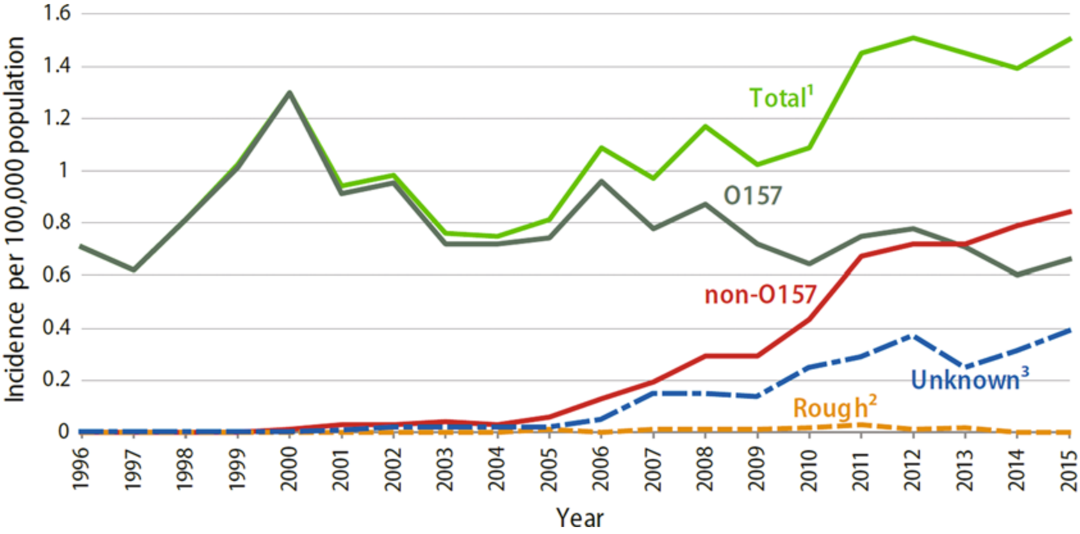

Fig. 1 Incidence rate of human STEC infection by serogroup and year, United States, 1996–2015. In the United States, the incidence of O157 infection decreased and the incidence of non-O157 infection increased since 2000. In 2015, the incidence of non-O157 STEC infection exceeded the incidence of O157 infection. (Reprinted with permission from reference [8])

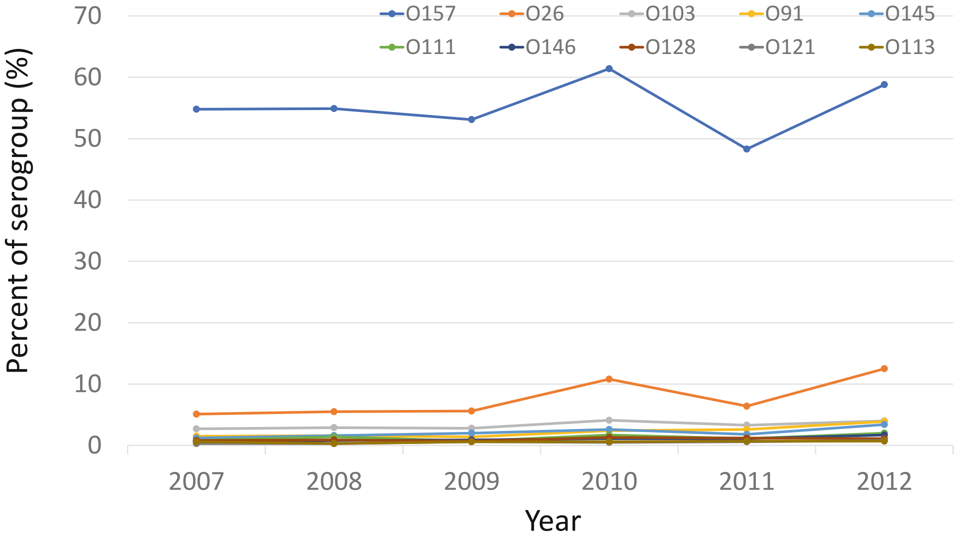

Fig. 2 Distribution of the ten most commonly reported STEC O-serogroups in confirmed cases as reported by EU/EEA countries, 2007–2012 (Reference [9, 17]). In EU/EEA, although O157 STEC infection is the most common and its incidence rate is stable, it accounted for only 55% of the identified cases from 2007 to 2012

as routes of transmission for STEC [21]. Another important transmission route of STEC is person-to-person transmission. Person-to-person transmission has been reported to be the second-most frequent transmission route of STEC after ingestion of undercooked or raw meat, and it is estimated that a complete suppression of transmission through person-to-person contact could reduce STEC infection by 15% [21]. As a result of the study for prevalence and serotypes of STEC in feces from about 473,000 healthy adults, including food handlers and person who worked in childcare facilities or nursing home, STEC was positive in 398 cases, and the incidence of asymptomatic carriers in healthy adults was estimated as 84.2 cases/100,000 person-year in Japan. Although the kind of serotype and characteristics of STEC detected from healthy adults differed from those detected from symptomatic patients, the presence of asymptomatic carriers in STEC suggests the possibility of person-to-person secondary infection as a route of transmission [10].

Diagnosis of STEC Infection

As confirmation of exclusion of STEC infection is essential for diagnosis of complement-associated HUS, selection of therapy, and estimation of prognosis, screening for STEC infection is recommended to be performed in all patients with HUS. STEC infection is led by a very low load of organisms (<100 organisms) [22], and excretion of STEC in the stool of patients generally lasts only a few days following the onset of diarrhea [12]. Therefore, stool samples should be obtained as soon as possible after the onset of diarrhea. If appropriate stool samples cannot be obtained, rectal swabs can also be collected [12]. STEC O157 is a non-sorbitol-fermenting representative strain of STEC that can be detected by the appearance of white colonies in culture on a sorbitol MacConkey agar plate. However, it should be noted that selective and differential detection using this method is not appropriate for the detection of non-O157 serotypes [12], which have been increasing in recent years. Once a STEC has been detected, its additional serotypes should be confirmed. To increase the identification rate of STEC infection, analysis of the genes encoding Stx (*stx1* and *stx2*) using PCR and detection of STEC and Stx using immunologic assays including ELISA should be conducted using incubated samples in enrichment culture simultaneously with the culture test for STEC detection [12]. In addition, the presence of anti-LPS antibodies in the serum of the patients who develop STEC infection, especially those who develop STEC-HUS, should be determined to carry out the serological diagnosis for the main STEC strain [12].

Characteristics of Stx

STEC produce two main types of Stx, known as Stx1 and Stx2 which were encoded *Stx1* and *Stx 2* genes. The strains of STEC can produce Stx1 and Stx2, alone or in combination. Each Stx is classified into subvariants, Stx1a, Stx1c, Stx1d, and Stx2a to Stx2k [23, 24]. The Stx2 is believed to be more virulent than Stx1, and Stx2-producing *Escherichia coli* is frequently detected in STEC-HUS patients either individually or with Stx1 production.

Stx is composed of a single subunit A and five subunit B. The subunit A is a biologically active subunit with 30 kDa of molecular weight and the subunit B is a cell recognition receptor binding subunit with a molecular weight of 7 kDa [22].

Mechanisms of Stx-Mediated Cell Injury (Fig. 3 [26])

Stx released by STEC in the intestine enters the circulation through the gastrointestinal epithelium. In the circulation, Stx is transferred to target organs such as the kidney, brain, and pancreas and express the specific Stx receptor, globotriaosylceramide 3 (Gb3) [26]. Gb3 is also known to be involved in the development of Fabry disease. By binding its subunit B to Gb3, Stx is internalized into the cells by endocytosis and transported in a retrograde manner to the endoplasmic reticulum. Thereafter, the subunit A translocates to the cytosol and interferes with ribosomal protein synthesis through the depurination of adenosine at 28S ribosomal RNA [26]. The inhibition of protein synthesis of the affected cells including endothelial cells leads to the apoptosis and eventual cell death. Platelets and coagulation factor deposition due to endothelial surface injury result in the formation of microthrombi and the TMA lesion which characterized HUS.

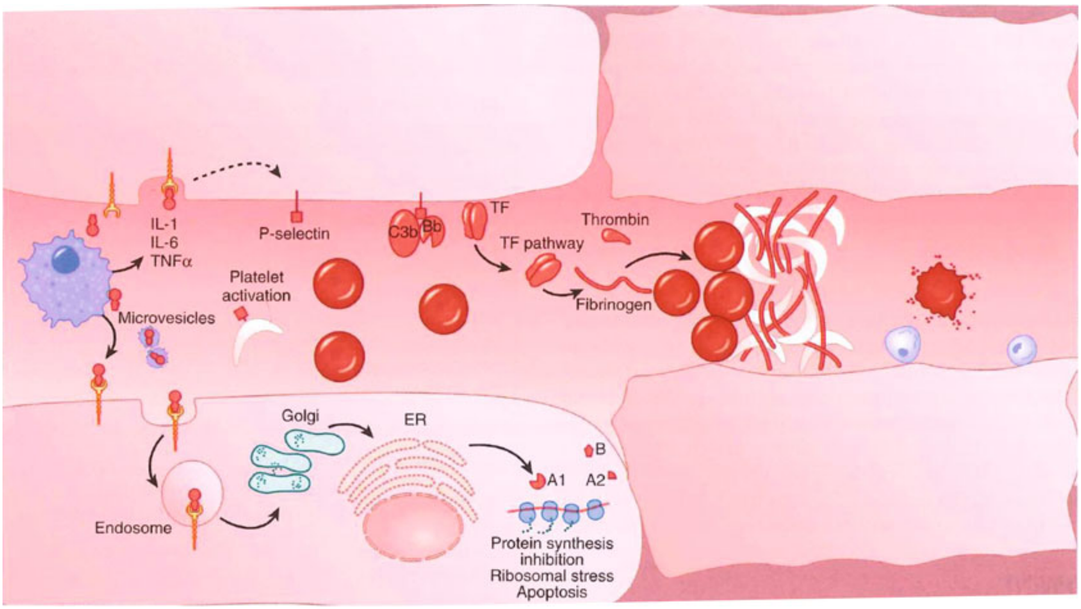

Fig. 3 Shema of Stx-mediated cell injury. In circulation, by binding subunit B of Stx to Gb3, Stx is internalized into the cell by endocytosis and transported in a retrograde manner to the endoplasmic reticulum. Thereafter, the subunit A translocates to the cytosol and interferes with ribosomal protein synthesis. The inhibition of protein synthesis of the affected cells leads to apoptosis and eventual cell death. Platelets and coagulation factor deposition due to endothelial surface injury result in the formation of microthombi and the TMA lesion. Reproduced from Kavanagh D, Sheerin N. Thrombotic microangiopathy. In: Yu ASL, Chertow GM, Luyckx VA, Marsden PA, Skorecki K, Taar MW, editors. Brenner & Recctor's the Kidney. 11th ed. 1178–95. Copyright 2020 Elsevier Masson SAS. All rights reserved

Stx-caused vascular injury stimulates thrombin release, resulting in increased fibrination, while increased plasminogen activator inhibitor-1 secretion by damaged vascular endothelial cells [27] inhibits fibrinolysis and promotes thrombosis. Exposure of Stx results in the rapid and persistent secretion of the unusually large von Willebrand factor (ULVWF) by vascular endothelial cells, thereby promoting the immediate adhesion of flowing platelets and the formation of large amounts of ULVWF-platelet strings. In turn, cleavage rates of plasma ULVWF-platelet strings by a disintegrin-like and metalloproteinase with thrombospondin type 1 motifs 13 (ADAMTS13) are decreased; thus, platelet thrombus formation is accelerated [28]. In addition, Stx induces the secretion of vasoconstrictor proteins by endothelial cells, such as endothelin-I [29], as well as various endothelial adhesion molecules and chemokines, which will promote leukocyte migration and adhesion [27]. Importantly, exposure to Stx increases the expression of Gb3 in targeted cells resulting in increased sensitivity to the toxin [30].

Involvement of Inflammatory Components

Although the pathogenesis of endothelial cell damage caused by inhibition of protein synthesis by Stx is necessary for the development of HUS, recent data has suggested that host factors, particularly inflammatory responses, are involved in the development and severity of HUS.

Polymorphonuclear Neutrophils

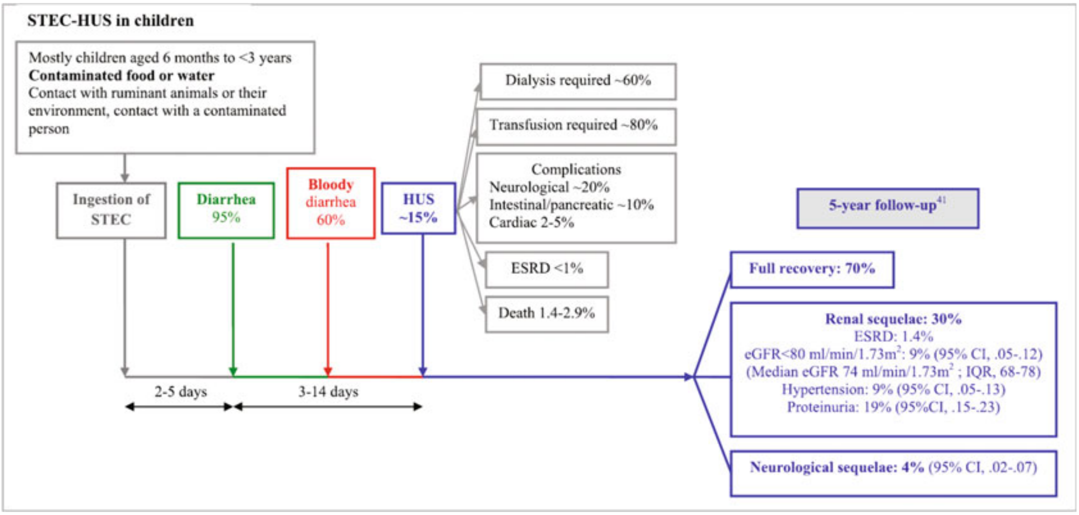
Increased peripheral blood leukocyte, particularly polymorphonuclear neutrophils (PMNs), was described as poor prognostic factors in HUS [31], suggesting a differential involvement of PMNs in HUS pathogenesis. Thus, it is believed that PMNs are directly involved in renal inflammation and endothelial cell damage via proteolytic enzymes released by degranulation and increased reactive oxygen species (ROS) production under the acute phase of HUS [32]. Oxidative stress is usually appropriately removed and balanced in vivo by endogenous antioxidants [33]. However, it has been reported the increase of thiobarbiturate reactive substances as indicators of lipid peroxidation [34], as well as higher levels of advanced oxidation protein products [35] and reduced superoxide dismutase activity [36], overall suggesting an oxidative imbalance in the acute phase of HUS.

Complement System

In some patients with STEC-HUS, low serum C3 levels [37] and increased factor Bb and soluble membrane attack complex (SC5b-9) [38] has been reported, suggesting at least transient activation of the alternative complement pathway. Additionally, it was shown in vitro that Stx binds to short consensus repeats 6–8 and 18–20 of complement factor H, impairing the alternative C3 convertase inhibition by factor H at the endothelial cell surface [12]. Therefore, Stx might directly activate complement alternative pathway in STEC-HUS.

Clinical Course (Fig. 4 [12])

The clinical manifestations of HUS are nonspecific, including fatigue, pallor, and decreased urine output. STEC-HUS frequently occurs after prodromal illness with abdominal symptoms due to STEC infection-associated gastroenteritis and enterocolitis. The symptoms of STEC infection-associated gastroenteritis such as abdominal cramps, diarrhea, nausea, and vomiting appear after an incubation period of 3–8 days (median 3–4 days) [39]. The predominant symptom is diarrhea, which usually starts as a non-bloody diarrhea, persists for 2–3 days, and progresses to bloody diarrhea in as many as 60–90% of STEC-infected cases [12, 40]. Abdominal pain is more severe in STEC infection-associated gastroenteritis than in other bacterial enterocolitis; additionally, defecation tends to be painful, but fever is rare [12, 40]. Moreover, STEC is rarely found to be invasive and detected in blood cultures. The



STEC-HUS in children
Mostly children aged 6 months to <3 years
Contaminated food or water
Contact with ruminant animals or their environment, contact with a contaminated person
Ingestion of STEC
Diarrhea 95%
Bloody diarrhea 60%
HUS ~15%
Dialysis required ~60%
Transfusion required ~80%
Complications
Neurological ~20%
Intestinal/pancreatic ~10%

colon can be quite severely affected, and the characteristic features of colon in patients with hemorrhagic colitis due to STEC infection are severe inflammation, primarily marked edema and easy bleeding, inflammation predominantly in the right side of the colon, and frequent appearance of longitudinal ulcer-like lesions as observed from the colonoscopic findings (Fig. 5) [41]. Abdominal computed tomography or ultrasonography [42] often shows swelling and thickening of the colon wall, particularly the right side of the colon [42] (Figs. 6 and 7). Diarrhea usually improves within approximately 1 week, and colon wall thickening improves gradually. Overall, 10–15% of patients with STEC infection develop HUS after a median interval of 7 days (interquartile range [IQR] 5–8 days) from the onset of diarrhea [31]. Once STEC infection has progressed to HUS, consumptive thrombocytopenia is observed as the first abnormality in most patients [40]. Hemolysis may result from mechanical fragmentation in passing through the turbulent blood flow in microvasculature due to partial occlusion by new platelet thrombi. Therefore, hemolytic anemia in STEC-HUS is Coombs negative, with the presence of schistocytes in the peripheral blood smear. The lactate dehydrogenase levels are elevated due to cell lysis, and haptoglobin levels are decreased due to the binding of free hemoglobin with haptoglobin and uptake by the reticuloendothelial system [25]. Although hemolysis in STEC-HUS generally precedes azotemia, some patients have shown elevated creatinine levels 1 or 2 days before the decrease in the packed cell volume [25, 40]. Oliguria and hematuria may result in anuria, depending on the

disease severity. In the acute phase, approximately 50–60% of patients require renal replacement therapy (e.g., dialysis) [12, 31], and more than 90% of patients require transfusion including transfusion of red blood cells (RBC), platelet, and fresh frozen plasma [12, 31]. Although the kidneys and gastrointestinal tract are the most commonly affected organs in HUS, various organs including the central nervous system, pancreas, skeletal muscle, and myocardium are involved. Among the affected organs, involvement of the central nervous system is the most life-threatening complication in HUS, and it occurs in 10–25% of patients with STEC-HUS [12, 42–44]. According to a meta-analysis, diabetes due to pancreas involvement occurs in 3.2% of patients with HUS [45], and ischemic cardiomyopathy, life-threatening condition, may occur in 2–5% of patients with HUS [12]. The mortality rate, mainly attributed to neurological complications, has been reported to be 1–3% [31, 46].

Severe gastrointestinal involvement can result in severe complications such as hemorrhagic colitis, toxic megacolon, and transmural necrosis of the colon with gastrointestinal perforation or colonic stricture [47–51]. These complications occur in approximately 5–10% of patients [12, 47, 50], and the right side of the colon, including the transverse and ascending colon, is the most commonly affected bowel segment [47]. Histopathological examination of the colon revealed hemorrhage, edema, inflammatory cell infiltration, and necrosis [48], and necrotic lesions were observed in more than 80% of the examined cases [47]. In addition, abundant terminal deoxynucleotidyl transferase-mediated dUTP nick-end labeling (TUNEL)-positive nuclei were observed in the tissue obtained from STEC-HUS patients compared with those of from controls [48]. These findings suggest abundant cell death due to apoptosis in the colon tissue of patients with STEC-HUS [48].

Pancreatic involvement in HUS more likely occurs in severe cases with central nervous system involvement or wherein acute dialysis is required [45]. A meta-analysis reported [45] that the incidence of diabetic complications in HUS in the acute phase was estimated to be 3.2% in the pooled incidence. Of 44 patients whose long-term outcomes were reported, 23% died in the acute phase, and 38% of the surviving patients remained diabetic, requiring insulin administration. Concerning the pathogenesis of insulin deficiency resulting in diabetes in HUS, the mechanism may be directly due to HUS with TMA of the pancreatic microvasculature [45], according to autopsy findings that TMA lesions were restricted to the islets of Langerhans with or without slight necrosis of the adjacent tissues [52].

Central nervous system involvement is common in HUS, and its symptoms including lethargy, irritability, seizures, cortical blindness, paresis, and coma have been reported in 10–25% of the affected children [12, 42–44]. Various complications associated with renal insufficiency, including hypertension, electrolyte abnormalities, and uremia, may contribute to the development of neurological manifestations [43]. Although the mortality rate in patients with HUS has decreased to less than 5% due to neurological symptoms, it has been reported that 54% [31] and 71% [46] of deaths were due to neurological involvement and that 17.3% of cases with severe neurological symptoms including coma and convulsion in the acute phase died and 23.1% had severe disabilities [53]. Therefore, it is still necessary to pay attention to the presence and severity of neurological manifestations complicated with HUS. In morphological analysis, the autopsy findings of the brain of 32 patients with HUS revealed random distribution of TMA throughout the brain in 11 cases [52]; the analytical findings of head magnetic resonance imaging (MRI) in HUS patients with neurological symptoms showed that all the structures of the central nervous system had the lesions [53]. However, no correlation was reported between the location of MRI abnormalities and the final prognosis [53].

For renal involvement, oliguria and hematuria may result in anuria, depending on disease severity. In the acute phase, approximately 50–60% of patients require renal replacement therapy (e.g., dialysis) [12, 31]. The mean duration of dialysis was 10 days (IQR, 6–15 days) [44]. Multivariate logistic regression analysis revealed that the longer the duration of dialysis, the higher the risk of presenting sequelae at 1-year, 2-year, and 3-year monitoring and that the median duration of dialysis was 15 days in children with long-term problems. The duration of dialysis required for children with long-term problems was longer than that in those without long-term problems (median duration: 9 days). These findings may suggest that the required dialysis period is a disease severity marker.

Long-Term Complications (Prognosis)

Owing to reduction in case fatality and improvement in the prognosis, chronic complications are more apparent in long-term survivors. It is reported that 1.4% of patients with HUS develop to end-stage renal disease [46], and 38% of survivors who were complicated with insulin-dependent diabetes mellitus required long-term insulin administration [45]. Additionally, 5 years after HUS diagnosis, approximately 70% of the patients fully recovered. However, the remaining 30% of patients showed neurological sequelae, persistent hypertension, or impaired renal function. Hypertension and proteinuria developed in 18% of patients who had no sequelae 1 year after the acute phase [46]. Therefore, long-term follow-up and care based on development of CKD is essential [46, 54].

Acute Management of HUS

STEC-associated HUS despite its relative rarity is still a major factor of morbidity for children and remains one of the most common reason of acute intrarenal kidney injury that requires dialysis in childhood [55].

Unfortunately, despite ongoing effort, there is still no specific cure or intervention for STEC-HUS. Therefore, foundation of therapeutic approach is the best symptomatic care that allows good glomerular perfusion and prevents long-standing damage to kidneys and other organs by providing adequate hydration, blood pressure control, and elimination of effects of nephrotoxic insults [56].

General Management of Patient with STEC-HUS

General aspect of treatment are symptomatic, following development and severity of the disease progression and its specific complications. Considering how rapidly the disease can progress from colitis to systemic manifestation of HUS with AKI, we would recommend that patients with developing STEC-HUS are admitted to a pediatric nephrology center with capacity for rapid initiation of renal replacement therapy and careful monitoring and backup of high dependency unit when severe central nervous symptoms develop.

The care follows patient symptoms, in the first instance development of acute kidney injury of variable degree. The general aspects of care for patients with AKI in terms of electrolytes management, fluids, and initiation of RRT should be followed; therefore, we recommend to follow appropriate recommendations in chapters on this topic. Patients usually require renal replacement therapy where both modalities – peritoneal and hemodialysis – are equal in terms of efficacy and risks. Continuous renal replacement therapy is also utilized, particularly in patients with severe presentation or complications or when cardiovascularly unstable. There is no specific proof that early RRT improves outcome.

Antihypertensive therapy might be necessary and could potentially reduce secondary cerebral complications like PRES. The usual recommendation is first-line treatment with calcium channel blockers. ACE inhibitors do not show specific advantage, and their use should be based on specific needs and risk of renal hypoperfusion.

Pain management avoiding NSAIDS and adequate nutrition support should be a routine part of care. Interestingly, fluid management showed some alleviation of abdominal pain. It is speculated that improved perfusion plays some role in it.

Antimotility agents are discouraged in STEC-HUS as they may prolong possibility of toxin exposure. On the opposite, bowel lavages or drugs speeding up the bowel content passage were suggested to decrease toxin exposure.

Fluid Management

In hemorrhagic enterocolitis due to STEC infection, dehydration often results from frequent diarrhea, severe abdominal pain, nausea, and decreased fluid intake due to vomiting. Recent studies have demonstrated that hemoconcentration and dehydration, which often coexist at HUS onset, are risk factors for more severe disease conditions including renal involvement [57, 58]. In addition, it has been reported that appropriate volume expansion using isotonic solution with careful monitoring of the patient's hydration state may be able to reduce or prevent severe HUS symptoms [59, 60]. A systematic review demonstrated that clinically dehydrated patients had an OR of death of 3.71 (95% CI, 1.25–11.03; $I^2 = 0\%$) and that intravenous fluid administration up to the day of HUS diagnosis was associated with a decreased risk of renal replacement therapy (OR 0.26 [95% CI, 0.11–0.60]) [61].

Hematological Symptoms Management and Treatment with Blood Products

Recommendation of blood products infusion is based on clinical need and is usually a necessary part of care in STEC-HUS patients. Packed RBC are given based on clinical grounds and symptoms of anemia like tachycardia and tachypnea. The cutoffs for transfusion is debated. ECUSTEC trial (https://www.birmingham.ac.uk/research/bctu/trials/renal/ECUSTEC/index.aspx) uses cutoff for hemoglobin of 70 g/L; however, some recommendations are based on symptoms of anemia or have much lower cutoffs and more guided by symptoms severity.

Thrombocytopenia is a defining hallmark of HUS and is seen as a complication for interventions, particularly need of placing a dialysis intravenous line or PD catheter. Platelet transfusion is used to reduce risk of bleeding; however, retrospective study has not showed increased risk regardless platelet infusion or lack of it [62]. Pathology of the disease call for caution in giving additional platelets as this can further fuel the process of microthrombosis. Retrospective study has not showed significant impact of platelet transfusion on HUS severity [63]; therefore, the platelet infusion should be weighted based on individual patient risks of bleeding.

Plasma infusion, plasma exchange, and immunoadsorption have showed some effect on neurological symptoms in single case reports; however, this was not demonstrated on larger samples [64]. Therefore, plasma therapy has not been found beneficial in children with STEC-HUS and could create even increased risk, particularly in smaller age groups [55].

Antibiotics in STEC-HUS

Antibiotic therapy is a matter of controversy and generally not recommended. In vitro studies show antibiotics lead to increased production and release of Stx, and prospective study and retrospective meta-analysis on more than 1000 children showed increased incidence in children receiving antibiotic. There was also no benefit seen in reducing other symptoms of STEC infection [65]. On the other hand, recent report separating different antibiotics showed detrimental effect of beta-lactams and trimethoprim/sulfamethoxazole and some benefit of fosfomycin and fluoroquinolones [66].

Special consideration is required in cases where intestinal gangrene develops, bacterial superinfection is suspected, or septic features are present. These situations need to be weighed on individual risk benefit for the patient.

Preventive Measures to Decrease Chance of Developing STEC-HUS and Additional Treatments and Therapies in Development

Beyond the currently recommended symptomatic approach, there is an ongoing effort to find a treatment or approach that will diminish the mortality and morbidity.

The disease still creates significant burden and remains without targeted treatment and preventive strategy except epidemiological interventions and infection prevention.

This unmet need creates an opportunity for developing strategies of reservoir elimination or immunization, prevention of toxin exposure, and most importantly for therapies that will stop and prevent further damage in already established endothelial injury. Despite numerous concepts summarized in recent review [67] (Table 3), there are very few of them that reached the level of clinical intervention or trial.

The epidemiological prevention and reservoir surveillance still has its place. Early identification and microbiological diagnosis of STEC can reduce and curb outbreaks when sources are identified rapidly [18].

Strategies to reduce reservoir infection by vaccination or specific diet given to cattle are in development but have not been largely implemented or tested, particularly due to rarity of complications and need of large-scale intervention in cattle and wild ruminants reservoir.

The second line in the concepts of preventing HUS lies in reducing toxin transfer in already infected individual from the gut to the bloodstream. Most advanced was a trial of Synsorb PK, which ought to bind toxin in the gut. Unfortunately, the trial has not showed benefit of the drug in children [68]. Similar conceived are trials where monoclonal antibodies or peptides should prevent reaching STx in the bloodstream to the areas with GB3 receptor [69]. These shown some promise in animal models; however, their practical usage seems limited due to very short window between infection and identification of the patients in risk of developing HUS and that our knowledge of precise location and activity of toxin in the pathogenesis is still sparse [67].

The final option of preventing damage of the STEC infection is to reduce final steps like inflammation and coagulation. Steroid treatment, IVIG, and anticoagulation and antiaggregating treatments were used in small studies, where they had not shown benefit [55].

Several reports indicated that in patients with STEC, alternative pathway of complement is activated, and levels of consumption in some report correlate with severity [70]. Eculizumab is a humanized anti-C5 antibody that blocks terminal pathway of complement and showed remarkable success in genetic complement-driven cases of atypical HUS [71]. Eculizumab showed promise to decrease extrarenal complications of STEC-HUS which was reported in seminal case series of three children [72]. However, large opened trial during the 2011 O104:H4 outbreak in Germany has not showed benefit of the drug in adults [64]. Several collated case series remain equivocal [73]. The conundrum might be resolved by two placebo-controlled randomized trials ECUSTEC (UK) and ECULISHU (NCT02205541 France) that are still ongoing and should report their results soon [74].

Streptococcus pneumoniae-Associated HUS

Non-STEC-HUS can be caused by other invasive infections such as the Gram-positive, encapsulated bacterium *Streptococcus pneumoniae* (*S. pneumoniae*). Primarily, it causes infections of the upper (sinusitis) airways but also otitis media and later lower airways (pneumonia). Its invasive and systemic form, IPD, causes multiorgan damage, like pulmonary empyema and meningitis. Some patients with IPD also develop HUS (P-HUS). Although P-HUS represents a low but significant number of all HUS cases, robust and definite data about pathophysiology, clinical course, treatment, and outcome are still lacking, which could partly be due to the fact that it is underdiagnosed in patients with IPD. During the

last years, it has become evident that P-HUS is caused by several factors and mechanisms.

Pathophysiology

A current concept is that in IPD, members of the bacterial neuraminidase enzyme family (NanA, NanB, NanC) lead to, by cleaving sialic acid (*N-acetylneuraminic acid*) from glycoproteins to the exposure of the normally hidden Thomsen-Friedenreich Antigen (T-Antigen, Galß1-3GalNac) on the surface of various cells, like erythrocytes or renal endothelial cells [75, 76]. The presence of one (*NanC*) as a predictor for the development of P-HUS as being additive to the presence of *NanA* and *NanB* has been proposed but has not been confirmed entirely [77]. As a condicio sine qua non, circulating, i.e., already existing or newly generated, antibodies of the IgM-Type detect and bind to the T antigen (TA) [78]. As a consequence, downstream immune mechanisms then damage or destroy T antigen-expressing cells (RBC, endothelial cells), leading finally to TMA and MAHA. Initially anticipated as being specific and sensitive for IPD-associated HUS, only 60% of all P-HUS and IPD patients are encountered with a positive Coombs Test [79–81]. Chen et al. described that 66% of patients with IPD were found to have TA activation, but TA activation was significantly correlated with HUS and a more severe clinical course [82]. On the other hand, only half of the TA positive patients did develop HUS. By using isolates of P-HUS patients, Meinel et al. found that pneumococci bind human plasminogen, mediated by the bacterial surface proteins Tuf (Elongation factor Tu) and PspC (pneumococcal surface protein C) [83]. When activated to plasmin at the bacterial surface, the active protease degraded fibrinogen and cleaved the complement factor C3b. Likewise, PspC, might act as pneumococcal plasminogen receptor. Plasmin generated on the surface of pneumococci, in turn, damages endothelial cells, exposes the underlying matrix, and engages complement activation.

Galectin-3 (Gal-3), an endogenous T antigen binding protein that links in high concentrations a supramolecular structure of cell surfaces and glycoconjugates, was found significantly higher in IPD patients when compared to normal healthy controls and was even higher in patients with IPD and P-HUS. As such, this mechanism could in turn lead to complement activation [84, 85].

In some of these studies, complement activation has been identified to play a role in the pathophysiology of IPD and P-HUS. Therefore, studies have focused directly onto the role of the complement system in pathogenesis and also treatment of P-HUS. It has been reported that complement activation via the alternative pathway can be triggered by desialylation on RBC [86–88]. In turn, the binding capacity complement factor H to C3 convertase, and this lack of inhibition leads to complement activation and endothelial damage [89]. Studies have shown that complement factor C3, in fact the only parameter that is readily available in the majority of hospitals, is decreased in several patients with IPD and HUS [90, 91].

Besides a transient dysregulation of the complement pathway, studies have also identified genetic factors that contribute to permanent activation, or states where, like in patients with aHUS, external factors trigger overt disease, like infections, malignant hypertension, or pregnancy. In clinical studies, variations and mutations in the complement pathway of some patients with IPD and P-HUS have been detected [92]. As more patients have been reported with variations in the complement system, it has been investigated if patients might benefit from the treatment with the C5 blocker, eculizumab.

Clinical Course

Pneumococcal vaccine coverage has increased by including more and more subtypes. In several countries, different vaccinations are available, like PPSV23, a polysaccharide-based vaccine which is restricted to patients of the age 2 years and older; the PCV10, a conjugation-based vaccine restricted to the age of 5; and PCV12, a conjugation-based vaccine with no age restriction. The latter includes also the serotype 19A, that has been reported as the most prevalent serotype in P-HUS (54.5%) in 2010 [80]. However, P-HUS is still most prevalent in younger children and mostly in those below the age of 2. A few days after the onset of fever and other IPD signs and symptoms, P-HUS manifests, in most of the cases between 3 and 13 days [93]. About 60% present with pneumonia-associated empyema (Fig. 8) and meningitis, which contributes per se to the high morbidity and mortality in this cohort and, certainly, to the rather poor outcome when compared to STEC-HUS [94]. P-HUS patients have, compared to STEC-HUS patients, more complicated clinical course. They were reported to have longer periods of oliguria and anuria, therefore a longer need for renal replacement therapies and need more days of intensive care [80, 94, 95].

Management

Although several molecular mechanisms of P-HUS have been identified, supportive management and targeted antimicrobial therapy represent still the major strategy as it is in all patients with infection-associated HUS. IPD-associated complications like lung empyema, effusions, and pneumothorax and the difficult airway management are often the limiting problems of treatment. Due to the concept of preformed IgM antibodies to the T antigen, washed RBC are still recommended. The beneficial use of IVIG by the

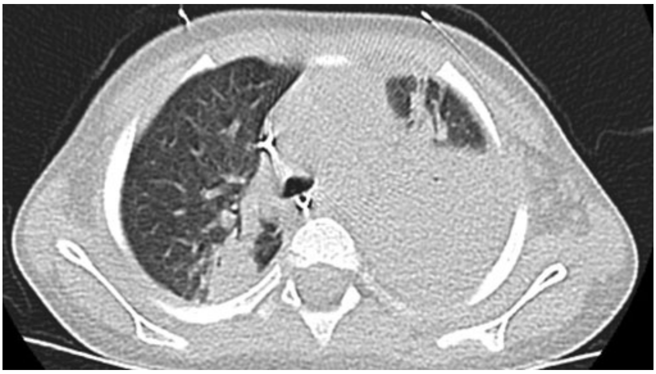

Fig. 8 An 18-month-old patient with P-HUS. The CT scan reveals heavy pulmonary involvement with effusion and empyema

concept to bind circulating neuraminidase has been reported [90]. The decision whether peritoneal or hemodialysis should be introduced is dependent on the patient's individual situation (availability of vascular access, bleeding complications, etc.). Especially, in the clinical situation of IPD and disseminated intravascular coagulation (DIC) and multiorgan failure, the coexistence of P-HUS should be vigorously searched for. In the presence of IPD and AKI, renal biopsy is often not helpful, since MAHA and TMA can be caused by other factors than P-HUS. As there is increasing evidence of transient or permanent dysregulation of the complement system in P-HUS, attention should be paid in the early introduction of C5 Blockers. Before initiation of complement inhibition (eculizumab or ravulizumab), complete diagnostics of complement (except genotyping) should be obtained. If the patient is not completely immunized against encapsulated bacteria (pneumococci, meningococci and *Haemophilus influenzae*), sufficient antibiotic coverage must be ensured. Moreover, other situations that could present with TMA and MAHA should be excluded, as other therapies are available (i.e., caplacizumab for TTP) [96].

HUS Associated with *Shigella dysenteriae* Type 1, Influenza Virus, and Other Infections

HUS Associated with *Shigella dysenteriae* Type 1

Shigella is a non-motile Gram-negative facultative anaerobic rod, belonging to the family *Enterobacteriaceae* [97]. In 1897, the microbiologist Kiyoshi Shiga identified this bacterium as the causative agent for dysentery during an epidemic in Japan, which was associated with high mortality [97]. Although mortality due to *Shigella*-associated diarrhea has declined substantially during the past three decades due to increased access to antibiotics and oral rehydration therapy, *Shigella* was the second leading cause of diarrhea-associated mortality in 2016 among all ages accounting for about 13.2% of all diarrhea-associated death [98]. In the 2012 EU/EEA surveillance report, the notification rate for *Shigella* was 1.8 cases/100,000 persons [9], and in 2016 the incidence of *Shigella* in the United States was reportedly 3.92 cases/100,000 person [99]. *Shigella* is an antigenetically diverse pathogen that comprises four species including *Shigella flexneri, Shigella sonnei, Shigella dysenteriae, and Shigella boydii*. *S. flexneri* is the leading cause of endemic shigellosis in low-income and middle-income countries. Further, *S. sonnei* has been reported as the second most common *Shigella* species in low-income and middle-income countries and the leading species in high-income countries. *S. dysenteriae* has reportedly almost disappeared since the late 1990s, with the United States reporting only 18 cases in 2016 (0.1%, <0.01/100,000 persons/year) and the EU/EEA reporting 132 cases in 2012 (2.3%).

Since HUS associated with *Shigella dysenteriae* was first recognized in Bangladesh in 1975 [100], nearly 500 cases of HUS in shigellosis outbreaks have been reported as of 2012 [101]. Although a small number of adult cases have been reported, most instances of HUS secondary to shigellosis are pediatric cases [101]. Despite relatively few case numbers, the literature has elucidated both diagnostic considerations for HUS and the likely clinical findings through the disease progression.

Manifestations of HUS develop late in the clinical course of shigellosis and may occur more than a week after onset of diarrhea. There are clinical reports that describe onset of bloody diarrhea due to shigellosis 4 to 17 days prior to the onset of HUS [101]. Diagnostically, leukocytosis and hyponatremia have been observed as likely preceding findings or associated signs of HUS other than the typically observed triad. According to Butler in summarizing seven reports, the incidence of HUS secondary to shigellosis ranged from 6–45%, with an overall incidence of 13% and a post-HUS mortality of 36% [101]. The incidence and mortality rate of HUS associated with *Shigella dysenteriae* type I are higher than those of STEC-HUS. *Shigella dysenteriae* type 1 has enteroinvasive properties that STEC does not and thus presents a higher risk for bacteremia, requiring a special focus on early treatment.

Appropriate antimicrobial treatment for HUS associated with *Shigella dysenteriae* type 1 during the early stages of infection, based on the specific drug sensitivity, is necessary [102]. It was reported that of 378 confirmed *Shigella dysenteriae* infection in which appropriate antimicrobial treatment started within 96 h, only one child developed HUS [103]. Furthermore, in 20 children with *Shigella dysenteriae* type 1 infection, fecal Stx was chronologically quantified after the onset of antibiotic therapy. In many cases, fecal Stx levels serially decreased and became undetectable at 72–120 h, and none of the 20 children developed HUS [103]. These results clearly support the recommendation for early treatment with appropriate antibiotics for *Shigella dysenteriae* infection.

Influenza Associated HUS and HUS Associated with Other Viral Infections

Influenza-associated HUS was first reported in 1971 [104], and since then, only 25 cases have been accumulated in the literature up until 2018 [105]. It is mostly associated with influenza A virus, specifically A (H3N2) and A (H1N1), with few reported cases associated with influenza B. In the literature survey [105], all 25 patients manifested the typical triad of HUS, 10 (40%) received renal replacement therapy, and 10 (40%) had central nervous system involvement. Of the seven patients who received it, all Coombs tests were negative. The prognosis was generally favorable with only three deaths (14%), and all but one surviving patient reported recovery of their renal function [105]. Although there is an established association between influenza virus infection and HUS, the underlying mechanisms remain speculative. The influenza virus has neuraminidase productivity like *Streptococcus pneumoniae*. However, in vivo neuraminidase released by influenza virus is expressed on the viral membrane at a lower quantity than *Streptococcus pneumoniae*, and its contribution to the pathogenesis of HUS has not yet been demonstrated. In addition, other factors such as direct injury and activation of vascular endothelial cells, platelet activation [106], and systemic complement activation [107] by influenza virus may be involved in the pathogenesis. In the literature survey [105], 8 of 25 patients underwent genetic screening, and the mutations in the gene for alternative pathway of complement were identified in 7 of the 8 patients, suggesting that influenza infection is a trigger for the development of HUS in patients with alternative pathway of complement regulator protein haploinsufficiency. Therefore, to clarify the pathogenesis of influenza-associated HUS, it is necessary to confirm the diagnosis of influenza virus and the disease type of TMA using measurements of ADAMTS13 activity, the identification of pneumococcus infection, the Coombs test, and genetic test for complement regulator protein.

It is reported that HUS has also been associated with HIV, cytomegalovirus, HHV6, parvovirus B19, and others [2].

Abstract

Acute post-streptococcal glomerulonephritis is the prototype for a postinfectious immune-complex mediated glomerulonephritis. Clinical manifestations follow a latent period of 1–6 weeks after a streptococcal skin or upper respiratory tract infection. Epidemic infections have been reported. Disease prevalence tends to be highest in economically disadvantaged geographic areas and populations. Disease pathogenesis has highlighted certain cell surface M virulence proteins and several putative nephritogenic antigens have been proposed, with activation of the complement pathway playing a key role. The disease phenotype is broad, ranging from asymptomatic microhematuria to a rapidly progressive glomerulonephritis (RPGN). Peak prevalence is in young school-aged children, with a preponderance of boys affected. Gross hematuria and hypertension are the most common clinical characteristics, with a third or more of affected children with oliguria or azotemia. Nephrotic syndrome is less common than a nephritic presentation. Depression of C3 complement levels and positive anti-streptolysin O and anti-DNAse B titers help to confirm the diagnosis. Kidney

biopsy is infrequently necessary, but typically reveals a proliferative and exudative glomerulonephritis on light microscopy, with C3 and IgG deposition on immunofluorescence, and subepithelial electron-dense humps as well as subendothelial deposits. Treatment is generally supportive, with focus on volume overload and hypertension, with most children recovering rapidly without long-term kidney residuals. Significant acute kidney injury requiring dialysis is usually associated with an RPGN with crescentic changes that is most commonly treated with pulse intravenous steroids, though there is no evidence-based support for immunomodulatory therapy.

Introduction

Acute post-streptococcal glomerulonephritis (APSGN) is the prototypical postinfectious immune-mediated glomerulonephritis. It is associated with a previous skin or throat infection, most often caused by group A streptococcus (*Streptococcus pyogenes*) and occasionally by streptococcus group C or G. APSGN is the most common form of glomerulonephritis in children, and like other diseases caused by group A streptococcus, it is seen disproportionately in economically disadvantaged populations [5].

APSGN is seen classically between 2 years of age and late adolescence, with primary school-aged children more frequently affected. Boys are afflicted twice as commonly as girls. The latent period between infection onset and nephritis has often been reported as shorter with respiratory illness (7–10 days) than skin infection (2–6 weeks), though there is little published clinical evidence that latent periods vary this broadly. Seasonally, respiratory illness-associated ASPGN predominates in the winter and spring whereas skin infection-associated ASPGN is seen more commonly in the summer and autumn. The typical clinical presentation for ASPGN is a classic nephritic syndrome characterized by hematuria, edema, hypertension, and oliguria.

The prevalence of APSGN varies widely and is influenced by geographic, socioeconomic, host, and bacterial factors. The incidence of APSGN has decreased worldwide, particularly in more economically advantaged countries. In developing countries, the annual burden of APSGN remains at a level of least 9 cases per 100,000 inhabitants [61].

Epidemiology

APSGN may occur in case clusters related to streptococcal epidemics or in isolated patients. Epidemic outbreaks as a consequence of both upper respiratory and skin streptococcal infections have occurred worldwide, with notable incidents in the Red Lake Reservation in Minnesota [2], in Port of Spain, Trinidad [47], in Maracaibo, Venezuela [54], and in the Northern Territory of Australia [31]. A recent epidemiological study of children with newly diagnosed nephritis reported that the children of indigenous people in Central Australia have the highest APSGN incidence, with nearly 40% diagnosed with a preceding streptococcal infection, predominately from a skin infection within the preceding month [18].

In recent decades, the reported incidence of APSGN has been declining, probably related to easier and earlier access to appropriate medical care for streptococcal infections in more areas of the world. In developed countries, there have also been reports of the overall severity of APSGN decreasing [24], while in certain high-risk indigenous population such as in French Polynesia, massive proteinuria, congestive heart failure, and kidney failure are still frequent features [9]. In children with a glomerulonephritis who undergo kidney biopsy, histology manifesting endocapillary proliferation such as expected with APSGN is the most common finding in children from economically disadvantaged areas and in areas with a high proportion of indigenous people [16, 31, 56].

The striking difference in APSGN incidence as a function of access to resources is underscored by the findings in one meta-analysis of 11 population studies that showed an ASPGN rate as high as 24.3 per 100,000 in less developed countries and as low as 2.0 per 100,000 in more developed regions. This study also estimated that over 470,000 cases of APSGN occur annually, with 97% in less developed countries [14].

Pathogenesis

APSGN is an immune complex-mediated disease that is not just due to a single streptococcal antigen and its antibody. Rather, kidney damage may be the result of different factors acting at the same time related to both streptococcus and host factors [35]. Several mechanisms may participate in the pathogenesis of kidney damage (Table 1).

Nephritogenic Antigens Traditionally, APSGN was considered to be caused by a nephritogenic antigen present in group A streptococci. *Streptococcus pyogenes* of M types 1, 2, 4, and 12 were associated with epidemic nephritis following upper respiratory infections, and M types 47, 49, and 55 were associated with epidemic nephritis following pyoderma. Nephritis may also follow infections with non-group A streptococcus as evidenced by an epidemic of group C streptococci in Brazil [7] and several similar clusters of cases [38].

Throughout the years, many putative streptococcal nephritogenic antigens have been studied without definitive confirmation of any causal relationship with glomerulonephritis [55]. The nephritogenic potential of streptokinase was investigated by in mice using the experimental tissue cage model, and demonstrated glomerular streptokinase deposits in association with hypercellularity, complement deposition, and proteinuria [39]. Subsequent studies by this group evaluated allelic variants of streptokinase using site-specific integration plasmids, and this work demonstrated the nephritogenic properties of the nephritis-associated streptokinase gene *ska I [40]*.

Presently, there is particular focus on two streptococcal antigenic fractions as to their nephritogenicity, the nephritis associated plasmin receptor (NAPlr) identified as glyceraldehyde 3-phosphate dehydrogenase (GAPDH) [42, 72], and the streptococcal pyrogenic exotoxin

Table 1 Pathogenetic mechanisms participating in acute post-streptococcal glomerulonephritis

Mechanism	Evidence	Reference
Nephritogenic antigens (NAPlr, SPEB, streptokinase, others)	NAPlr and SEPB demonstrated in renal biopsies	[40, 42, 48]
Circulating immune complexes	Circulating anti-SPEB and anti-NAPlr antibodiesin APSGN patients	[46, 72]
In situ Immune complexes (cationic antigens)	SPEB co-localized with complement in glomeruli and demonstrated in the subepithelial electron-dense deposits (“humps”) in APSGN	[7]
Autoimmunity (anti-IgG, other)	Neuraminidase is produced by some nephritogenic streptococci. Serum neuraminidase activity in APSGN patients	[4, 54, 59]
Anti-Ig (induced by the loss of sialic acid of the IgG or binding of the Fc fragment of IgG to type II receptors on the surface of group A streptococcus)	Serum anti-IgG titers; Renal anti-IgG deposits	[13, 46, 54, 58]
Other autoimmune reactivity	Anti-DNA, anti.C1q, ANCA and anti-cardiolipin antibody demonstrated in serum	[3, 20, 29]
Other		
Increased plasmin activity in glomeruli (facilitating immune complex deposition	Co-localization of plasmin and NAPlr in glomeruli. Increasedurinary plasmin activity	[41, 42, 72]
Neuraminidase-induced glomerular infiltration of desialised leukocytes	Desialised leukocytes accumulate in the glomeruli of patients with APSGN	[30, 34]

(erythrotoxin) B (SPEB) and its zymogen precursor (zSPEB).

Work by Fujino et al. [19] has shown that the expression and gene sequence of NAPlr is present in streptococci from several groups. Anti-NAPlr antibody levels are found in 92% of the sera from convalescent APSGN patients and in 60% of the uncomplicated streptococcal infections in Japan [72]. NAPlr is present in early biopsies of APSGN, and since it is not co-localized with complement or IgG, its role as a nephritogen is thought to be related to its plasmin-binding capacity which facilitates immune complex deposition and inflammation [42].

The nephritogenic potential of plasmin-binding activity has been noted not only in NALPr but also in SPEB, streptokinase, and enolase. Some feel that this property may represent a common nephritogenic property of both NALPr and SPEB, since both of these antigens were identified by their group in the mesangium of biopsies of APSGN [41, 57, 72]. Along with this possibility, patients with APSGN exhibit an increase in urinary plasmin-like activity [41, 42].

SPEB, an extracellular cysteine proteinase, is a cationic antigen that is co-localized in the glomeruli with complement and Ig deposits. SPEB is the only streptococcal antigen that has been demonstrated within the electron dense subepithelial deposits (humps) that are the hallmark of APSGN [8]. Many studies have postulated that this localization is facilitated by the cationic charge of this antigen [69]. High anti-SPEB/zSPEB antibody titers have been found in the vast majority of convalescent sera sampled from APSGN patients in Latin America [46]. SPEB/zSPEB induces chemotaxis and increases angiotensin II production by mesangial cells [68]. Recent studies have demonstrated that the Fc portion of antibodies directed to SPEB binds to the C-terminal domain (rSPEB 345-398), and immunization with this domain prevents group A streptococcal infection in mice [65].

The attractiveness of a charge-related GBM injury in the pathogenesis of APSGN has led Zhang et al. [74] to examine if histones that are cationic elements may be part of the pathogenesis of APSGN. These studies showed that histones enter the circulation after streptococcal lysis and are capable of inducing in situ immune-complex formation.

Finally, recent evidence suggests that there is not a single nephritogenic antigen, since studies have shown that the gene that encodes for SPEB was absent in the *Streptococcus zooepidemicus* isolated from patients in a Brazilian epidemic [10]. Notably, in studies of this *Streptococcus zooepidemicus* strain, 33 of 44 APSGN patients were seropositive for the Szp5058 fusion protein that was isolated from the causative streptococcal strain [38], leading to speculation that the anti-phagocytic properties of Szp proteins may play a role in the pathogenesis of glomerulonephritis. Both NALPr and SPEB are capable of inducing monocyte chemoattractant protein 1 (MCP1) and IL-6 in mesangial cells [15, 27] and SPEB elicits the release of a variety of cytokines and interleukins from peripheral blood leucocytes [67].

Humoral and Cellular Immunity Activation of the complement system is a consequence of the glomerular antigen/antibody reactivity. The alternative complement pathway is usually most active in APSGN, with depression of C3 complement levels, although some may also have a reduction in C1 and C4 levels. In these patients, Protein H, a surface streptococcal protein, in combination with IgG may activate the classical complement cascade [11]. In addition, in some patients there may also be complement activation by the lectin pathway [43], but APSGN may also develop in individuals who are genetically unable to activate this pathway [62].

In addition to humoral immune initiation, cellular immune mechanisms are also activated in APSGN. It has long been known that there is cellular adhesion molecule (ICAM-1, LFA-1) overexpression with infiltration of lymphocyte and macrophages in the glomeruli of these patients [44, 45]. Higher numbers of CD4-positive lymphocytes are present in renal biopsies obtained in the first 3–4 weeks of disease and decrease in frequency afterwards [44]. Increased glomerular expression of IL-8 has been found to correlate with neutrophil infiltration and transforming growth factor–β expression with mesangial expansion [32].

Autoimmune Reactivity A number of autoimmune findings have been reported in APSGN, most notably anti-IgG reactivity. In the first week of disease, rheumatoid factor cryoglobulins are present in about two-thirds of patients. Furthermore, anti-IgG glomerular deposits are frequently found on biopsies, and anti-IgG reactivity has been documented in the IgG eluted from the kidney in a fatal case of the disease ([54]; [55]).

The anti-IgG reactivity may be the result of autoantigenic modification mediated by Ig desialization caused by streptococcal neuraminidase. This possibility was raised by studies showing that injection of neuraminidase-treated autologous IgG prompts the appearance of anti-IgG reactivity as well as by the demonstration of plasma neuraminidase activity and increased free sialic acid levels in patients with APSGN. Another potential cause of anti-Ig reactivity is the binding of IgG to type II receptors in the streptococcal wall. Anti-IgG reactivity is a constant feature of injections of streptococci cultured in a medium with autologous serum.

Additional autoimmune phenomena have been found in APSGN patients. Anti-DNA and anti-Ciq antibodies along with anti-neutrophil cytoplasmic antibodies (ANCA) can sometimes be present. Interestingly, ANCA has been found in up to 70% of ASPGN patients with azotemia or crescentic glomerulonephritis [3]. An autoimmune hemolytic anemia secondary to anti-cardiolipin antibody has also been reported [20].

Genetic Aspects A genetic aspect to disease susceptibility has been suggested by a higher rate of disease in siblings than rates seen in the general population during epidemics [59]. APSGN has also been associated with HLA-DR4 and DR-1 [54] and genetic mutations in the complement factor H (CFH) gene have been suggested as a cause for inducing dense deposit disease after an episode of PSGN [51] as well as a chronic glomerulonephritis triggered initially by streptococcal infection [66].

Clinical Characteristics

Children from 4–14 years old are most frequently affected by APSGN, and it is infrequently seen below the age of 2 years or above the age of 20 years. Boys develop APSGN with twice the frequency of girls. APSGN usually follows a respiratory or skin streptococcal infection, though any site of infection can be a potential trigger. Anecdotally, greater latency between infection and nephritis is reported after skin infection (3–6 weeks) than respiratory infection (1–2 weeks).

During the latent period, asymptomatic children may have microscopic hematuria. The subsequent clinical course of ASPGN varies from a subclinical disease to an acute nephritic syndrome, with an accompanying nephrotic syndrome or a rapidly progressive crescentic glomerulonephritis also potentially present [54]. Although subclinical disease with hypocomplementemia and microhematuria is clinically asymptomatic, it can be accompanied by increased blood pressure. In epidemic conditions, it has been estimated that subclinical disease occurs 1.5 times more frequently than clinically apparent disease [2]. In non-epidemic situations, prospective studies of household members of index cases have shown that asymptomatic patients are up to five times more frequent than symptomatic patients [17, 59].

The most typical symptomatic clinical picture in APSGN is the acute nephritic syndrome (hematuria, edema, hypertension, and moderate proteinuria). Glomerular hematuria is an almost universal finding and gross hematuria is present in one-third of patients. On urinalysis red cell casts are present in association with dysmorphic red cells. Macroscopic hematuria usually disappears within days, but microscopic hematuria may persist for a year or more and can exacerbate during illness and more rarely after strenuous exercise.

Edema is seen in up to 90% of symptomatic children, with anasarca infrequent outside of younger children and ascites uncommon except with concomitant nephrotic syndrome. Hypertension is present in 60–80% of the children and is severe enough to require specific antihypertensive treatment in about half of the cases. Oliguria on presentation is reported in up to half of symptomatic children. Other nonspecific symptoms include general malaise, nausea, weakness, headache, and dull lumbar pain.

Edema and hypertension typically abate within the first few weeks. Persistent heavy proteinuria is a risk factor for progression to chronic kidney disease. Although alterations of GFR with azotemia occur in 25–30% of patients, the need for dialysis is infrequent. A rapidly progressive course occurs in less than 1% of the cases and when present is due to the development of crescentic glomerulonephritis.

Pathophysiology of the Acute Nephritic Syndrome The acute nephritic syndrome stems from the inflammatory reaction in the glomeruli. Although renal blood flow is usually normal, the filtration fraction can be depressed to below 1%. While the reduction in glomerular filtration has long been assigned a central role in any fluid retention with an acute glomerulonephritis, modulation of tubular sodium and water handling including changes in the expression of the epithelial sodium channels and increased intrarenal angiotensin activity has been described [26], [28], [60].

Sodium and water retention results in expansion of the extracellular volume, with ensuing edema and hypertension. Plasma levels of renin, angiotensin, aldosterone, and atrial natriuretic peptide reflect an expanded extracellular volume, with the extent of suppression of plasma renin activity and aldosterone and the stimulation of atrial natriuretic peptide correlated with the severity of edema. Renal prostaglandin and kallikrein activities are also suppressed [54].

As glomerular inflammation decreases, the factors promoting volume retention moderate. The subsequent development of spontaneous or induced diuresis results in reduction in edema and correction of high blood pressure.

Serological Findings With APSGN the most constant serological finding is a reduction in serum complement levels that occurs in more than 90% of cases. The complement system is usually activated via the alternative complement pathway with reduced C3 complement levels as well as C1 and C4 complement. The classical and the lectin pathways of complement activation may also be engaged, however, and there are no clinical characteristics associated to a specific complement pathway's activation. Complement levels return to normal usually within 1 to 3 months after the development of acute glomerulonephritis, reflecting the tendency for a rapid spontaneous improvement in disease activity.

IgG and IgM serum levels are elevated in 80–90% of patients with APSGN. An elevated anti-streptococcal antibody titer is the usual laboratory confirmation of a preceding streptococcal infection since positive cultures are obtained in only 20–25% of cases, except during epidemics. Anti-zSPEB/SPEB serum titers have been found to be the best markers of nephritogenic streptococcal infections in multicenter studies based in Latin America [44], but these tests are not widely available to most clinicians, and anti-streptolysin O and anti-DNAse B titers are most frequently assayed. Two-thirds of ASPGN patients in the first week of disease may also manifest cryoglobulins and elevated IgG-anti-IgG rheumatoid factor titers, though again these studies are less commonly assessed [54].

Pathology Renal biopsy is seldom done in patients with APSGN. Biopsy is indicated when specific features raise the possibility of a different diagnosis, for instance if the serum complement is normal at presentation or stays persistently depressed several months after diagnosis. In the setting of rapid progression of kidney failure and concern for crescentic glomerulonephritis, the diagnosis also needs biopsy confirmation.

Light Microscopic Findings In APSGN, light microscopy usually reveals a diffuse proliferative glomerulonephritis (GN). The glomeruli are often enlarged and show global endocapillary hypercellularity. Some cases will show focal endocapillary proliferation or just mesangial proliferation [37]. In the acute phase of the disease, the GN also tends to be exudative, with a

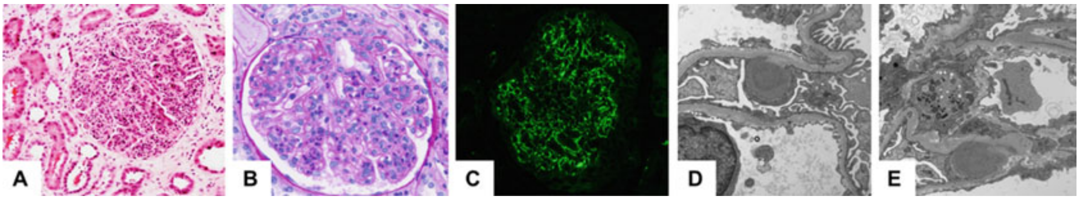

Fig. 1 **Pathology of Acute post-streptococcal glomerulonephritis**. (**a**). Acute post-streptococcal glomerulonephritis (APSGN) with severe proliferative and exudative GN. The glomerulus is enlarged and markedly hypercellular with a large number of neutrophils. Note the red blood cells in some tubular lumens. Hematoxylin and eosin stain, original magnification x200. (**b**). The glomerulus shows endocapillary hypercellularity with multiple neutrophils, although far fewer than the glomerulus in Fig. 1. Periodic acid-Schiff stain, original magnification x400. (**c**). Immunofluorescence staining for C3 in APSGN. There is granular staining in the glomerular capillary walls and mesangium, in a "starry-sky" pattern. Fluorescein isothiocyanate conjugated anti-human C3, original magnification x400. (**d**). Electron-microscopy in APSGN. Note the large, "hump"-like subepithelial deposit. The periphery of this deposit is slightly less electron-dense than its center, indicating very early resorption. The glomerular capillary with the subepithelial "hump" also contains a small subendothelial deposit. The glomerular basement membranes themselves are unremarkable and the podocyte foot processes are partially effaced. Uranyl acetate and lead citrate stain, original magnification x7500. (**e**). Electron microscopy in subacute post-streptococcal GN. A large, "hump"-like subepithelial deposit is present in a mesangial waist region; deposits are also present within the adjacent mesangial matrix. Uranyl acetate and lead citrate stain, original magnification x6000.

variable but oftentimes large number of neutrophils, as shown in Figs. 1a and 1b. After the first few weeks of disease, there is a progressive decline in cellularity, initially from the loss of the neutrophils, and a predominant mesangial proliferation persists.

In the acute phase of the disease, there is also often interstitial inflammation, which is typically comprised of a mixture of lymphocytes, monocytes, plasma cells, and neutrophils. Histologic evidence of acute tubular injury, characterized by the flattening of proximal tubular epithelium with loss of brush borders and nuclear enlargement, is also common. In adults, mild to moderate arteriosclerosis is generally seen, and in cases with underlying diabetic nephropathy, severe arteriosclerosis with arteriolar hyalinization and thickening can be found [37].

Immunofluorescence Microscopy Immunofluorescence findings in evolving APSGN have been elegantly defined [63]. In the first few weeks of the disease, fine granular deposits of C3 and usually IgG are found in the glomerular capillary walls as well as in mesangial areas, in what has been termed a "starry sky" pattern (Fig. 1c). Later in the disease, with resorption of many of the capillary wall deposits, there is a predominantly mesangial pattern of staining with a predominance of C3. Coarse to confluent granular staining along the glomerular capillary walls in what is termed the "garland" pattern can also be seen [63]. It is this pattern that best shows the individual subepithelial "humps" that are the characteristic ultrastructural feature of this disease.

In both acute and subacute post-streptococcal GN, deposits of C3 are invariably present, accompanied by IgG in most cases, and by IgM in approximately 50%, although the latter staining tends to be of low intensity [37, 61]. IgA staining is uncommon and of low intensity when present, although IgA is often the dominant immunoglobulin present in post-staphylococcal GN [22, 37, 36, 61]. C1q staining, typically of low intensity, can be seen in approximately one-third of cases [37]. Staining for light chains tends to follow the findings for IgG, with similar staining intensity for both kappa and lambda. If crescents are present, blotchy fibrinogen staining is typically noted at the periphery of the glomerular tuft and in a focal and segmental pattern.

Electron Microscopy The characteristic ultrastructural findings of APSGN are large subepithelial electron-dense deposits with a "hump-like" appearance, as shown in Fig. 1d. The number of these deposits varies considerably, and they can be segmentally limited or rather numerous, although not so common as to mimic a membranous nephropathy. The size of the subepithelial "humps" also varies considerably within any given glomerulus. In early postinfectious lesions, these deposits tend to be concentrated at or near the glomerular basement membrane reflection over mesangial areas, what is called the mesangial "waist" or "notch" (Fig. 1e) [23]. In resolving cases, the fraction of subepithelial deposits localized to mesangial waist areas increases further as more peripheral deposits are resorbed ([21]; [37]; [63]). Mesangial deposits are also abundant in the great majority of APSGN cases, as are subendothelial deposits though these tend to be smaller and more segmental in distribution ([37]; [61]). Extraglomerular deposits are not a feature of this disease.

Diagnosis

The typical clinical presentation is the sudden onset of dark urine with the development of swelling of the face and legs, oliguria, and hypertension. A history of a preceding upper respiratory or skin infection suggests a poststreptococcal etiology that may be confirmed by a positive streptococcal culture or rising anti-streptococcal antibody titers.

Positive streptococcal cultures are frequent in epidemic conditions but are found in fewer than 25% of sporadic cases. Throat swabs for streptococcal culture should be done in the setting of symptomatic pharyngitis, but are otherwise of limited utility. Evidence of a previous streptococcal infection usually depends on the demonstration of an elevated titer of serum antistreptococcal antibodies. Anti-streptolysin O and anti-DNAse B titers are the most frequently elevated in upper respiratory infections and impetigo, respectively. The streptozyme test which includes four antigens (DNAse B, Streptolysin O, hyaluronidase, and streptokinase) is reported to be positive in more than 80% of the cases.

Since a preceding infection may have been subclinical or so mild as to not be recalled, although ASPGN is the most common reason for a nephritic syndrome in a child, when there is not a compelling history of preceding illness, it is important as part of the initial diagnostic approach to assess if the acute nephritic syndrome is associated with a systemic condition with other manifestations or if it results from a primary renal disease. Determining complement levels allows there to be a relatively rapid determination if there is a hypocomplementemic GN, in which case conditions such as lupus nephritis, shunt nephritis, endocarditis, and the C3 glomerulopathies may also need to be considered in addition to APSGN. Normal complement levels and the nephritic syndrome can be found with IgA nephropathy and Henoch-Schonlein purpura, hemolytic uremic syndrome, vasculitis, and anti-glomerular basement membrane disease. In APSGN, serum complement levels return to normal quickly, often within a month and almost always within 3 months. Persistence of low complement levels should raise suspicion for a diagnosis different from APSGN and may prompt a kidney biopsy.

Treatment

Antibiotic Treatment If streptococcal infection is present at the time of diagnosis, it should be treated with penicillin or some other effective antibiotic. In epidemic situations and in high-risk settings, the administration of preventive antibiotic treatment to household members of index cases has been shown to decrease the number of subsequent APSGN cases [25].

Early administration of penicillin to infected children is reported to prevent or ameliorate the severity of acute glomerulonephritis, and at least one report suggests that APSGN patients who receive antibiotic treatment have a milder clinical course [75]. If active infection is not apparent at the time of diagnosis, antibiotic treatment is generally not provided to a child with APSGN. Since cross infection of household members and siblings of index cases can be very high, there does need to be attention to screening any symptomatic individual and treating with antibiotics if indicated [59]. If throat swab streptococcal culture is not readily available for symptomatic index cases or their symptomatic contacts, then empiric antibiotic provision is often provided.

Therapy with penicillin provided intramuscularly or orally is usually adequate treatment. Erythromycin is typically the treatment of choice in patients allergic to penicillin, although it should be noted that the existence of erythromycin-resistant strains may be increasing in many areas of the world, so a knowledge of local antibiotic-resistance patterns can help determine most effective empiric therapy ([12, 52, 53, 64].

Prophylactic antibiotic treatment is indicated in epidemic situations and may be considered in household members of actively infected index cases in non-epidemic conditions. Serologic evidence of recent streptococcal infection can be high in household members, and some reports have noted that in some situations up to one-third of household members may manifest some degree of nephritis [2, 54]. Especially in high risk communities, this strategy of treating household contacts may result in fewer cases of APSGN [25].

Treatment of the Acute Nephritic Syndrome Historically, children with APSGN often were made to restrict physical activity, including prolonged periods of bedrest. There is no evidence to support bed rest or activity restriction, especially if the blood pressure is not severely elevated and the child is feeling well.

To help prevent exacerbation of volume overload, sodium and fluid restriction are the most important initial steps for any child with acute nephritic syndrome. Loop diuretic provision can accelerate the resolution of edema and improve hypertension [50] whereas thiazide diuretics are generally far less effective. Oftentimes, diuretic therapy is needed for only a very short period of time.

In terms of blood pressure therapy, vasodilator therapy with calcium channel blockers or with hydralazine can be effective for significant blood pressure elevation. Aldosterone antagonists carry the risk of hyperkalemia, especially if there is any reduction in GFR. Similarly, angiotensin-converting enzyme inhibitors and angiotensin receptor blockers also carry the risk of hyperkalemia or exacerbating any reduction in GFR.

On occasion, continuous infusion of a calcium channel blocker, nitroprusside, or labetalol may be needed to treat a hypertensive urgency or emergency. Posterior reversible leukoencephalopathy syndrome (PRES) has been described complicating APSGN and can present with mental disturbances, visual hallucinations, headache, and convulsions [1]. PRES requires head MRI examination to confirm its diagnosis and rule out other causes of encephalopathy.

Pulmonary edema may occasionally complicate the clinical course, and if unresponsive to diuretic therapy and other medical maneuvers may necessitate urgent dialysis for ultrafiltration. Dialysis may also be needed for those children with severe azotemia, hyperkalemia, or acidosis that does not respond to other medical therapy, as well as with children with significant loss of kidney function as occurs with a rapidly progressive glomerulonephritis (RPGN) as a consequence of APSGN.

With an RPGN picture and a kidney biopsy with crescentic change to a significant number of glomeruli, many clinicians will provide pulse dose methylprednisolone intravenously followed by some course of high dose oral steroids that are gradually tapered. No randomized trials exist to support this approach, and this management stems from historic general approach to RPGN prior to the ability to discern a specific diagnosis through biopsy or serology. There is also no evidence to support other immunomodulatory therapy either acutely or long-term in APSGN, especially if there is rapid improvement in kidney failure. Although an immune-mediated pneumonitis has been described in PSGN [71], this is thought to be exceedingly rare, and no other immunologic anomalies requiring immunosuppressive therapy have been described.

Prognosis

Most children recover quickly from APSGN, with significant initial medical morbidity or mortality usually a result of hyperkalemia or pulmonary edema early in the disease course. Long-term prognosis is also generally good, though as with any illness that predisposes to acute kidney injury, there is some risk of chronic kidney disease.

Initial studies in the first half of the twentieth century reported complete recovery in affected children, but the follow-up periods were short. Subsequent observations found that abnormal urinary findings could be seen during follow-up in anywhere from 3.5% to 60% ([6, 49]. A recent report found that 20% of patients followed for 10–20 years after APSGN manifested an abnormal urinalysis, though GFR decline occurred in fewer than 1% [57]. Another study of 110 Chinese children followed for 15–18 years after presentation reported non-nephrotic proteinuria in 7.2%, microhematuria in 5.4%, hypertension in 3%, and altered GFR in 0.9% [44]. Studies in Australian communities of indigenous people indicate that APSGN patients have an increased risk on follow-up for albuminuria (adjusted odds ratio 6.1, 95% CI 2.2–16.9) and hematuria (OR 3.7, CI 1.8–8.0) in comparison to controls who did not have APSGN [57].

The long-term kidney prognosis after APSGN may be significantly influenced by any other risk factors for chronic kidney disease that an affected child may hold. For instance, the superimposition of APSGN on conditions such as diabetes and metabolic syndrome have been postulated to play a role on the high incidence of end stage kidney disease in some communities of indigenous people in Northern Australia [70]. It has also been reported that persisting arterial stiffness, as determined by brachial–ankle pulse wave velocity, is more common in patients with who develop chronic kidney disease after APSGN [73].

Abstract

The pathogenesis of infection-related renal complications in children is multifactorial and includes direct invasion of renal parenchyma, stimulation of an immune reaction, injury to the capillary endothelium, induction of a humoral response, or nephrotoxicity associated with the therapy of choice. This chapter presents non-streptococcal bacterial, fungal, and parasitic infections, some of which occur predominantly in tropical and subtropical regions, but which have been increasingly diagnosed in other regions of the globe on account of travel mobility.

Introduction

In this chapter, we will limit the discussion to non-streptococcal bacterial infections that include staphylococcal infection associated glomerulonephritis (SAGN) and other infections such as endocarditis, shunt nephritis, and visceral abscesses. Viral infection-related kidney involvement, post-streptococcal glomerulonephritis, and central venous catheter-related infections are described elsewhere.

Bacterial Infections

Renal involvement secondary to bacterial infection is multifactorial in nature and includes direct invasion of renal parenchyma, stimulation of an immune reaction, injury to the capillary endothelium, or induction of a humoral response (Fig. 1). Monocyte activation is triggered by bacterial infections (e.g., post-infectious glomerulonephritis) that stimulate T-cell and B-cell responses, leading to immune complex-mediated glomerular injury. Inflammatory responses, secondary to infection can cause interstitial injury and acute tubular necrosis (e.g., leptospirosis). Mechanisms for renal ischemia and acute tubular necrosis in bacterial infections include hypovolemia, endothelial injury, disseminated intravascular coagulation, hemolysis, and complement activation [1].

Tropical Infections

Tropical infections are important contributors to the burden of acute kidney injury (AKI) mainly affecting the continents of South America and South Asia [2, 3]. Organ involvement including the kidney is underreported despite the risk of mortality and morbidity associated with these infections. There is a need to increase awareness of these infections and their sequelae as these regions could continue to face the challenges of climate change, water and sanitation issues, antimicrobial resistance, and delay in diagnosis or treatment, leading to a potential risk for chronic kidney disease (CKD) development.

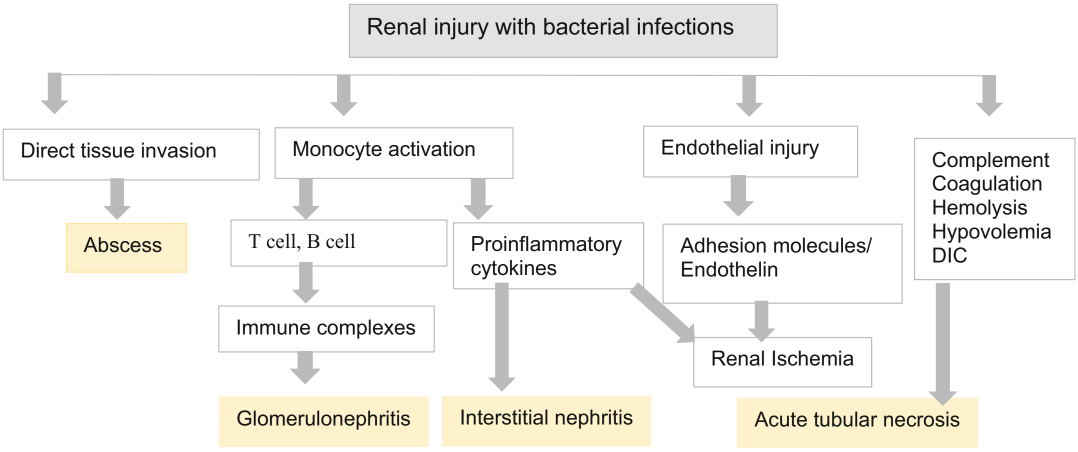
Tropical bacterial and protozoal infections can manifest with urinary abnormalities and AKI. Leptospirosis, malaria, dengue illness, scrub typhus, and bacterial gastroenteritis are notable infections associated with renal involvement in the tropics. These infections commonly present as a febrile illness with a wide spectrum of other systematic features including jaundice, rash, splenomegaly, myalgia, respiratory symptoms, and thrombocytopenia [3]. The notable tropical bacterial infections, their renal involvement, and key renal pathological features are listed in Table 1 [1, 4–7, 12–14].

Seasonal changes can contribute to infections. A spectrum of bacterial infections causing AKI in adults during the monsoon season in India was noted to be acute gastroenteritis (23%), leptospirosis (13%), and typhoid fever (3.5%). In children, a study in South India revealed non-cholera diarrhea (7.8%), cholera (3%), typhoid fever (2.4%), scrub typhus (1.8%), tuberculosis (1.2%), and leptospirosis (0.6%) to cause AKI [8, 9].

Acute gastroenteritis was the most common diagnosis for AKI (44–60%) in hospitalized children from Argentina and Uganda [10]. However, the precise organism (bacterial/viral) causing diarrheal disease is commonly not evaluated in most developing countries. The reader is directed to the chapter on hemolytic uremic syndrome for details on bacterial diarrheal disease caused by *Escherichia coli*, Shigellosis, and *Campylobacter* species.

Tuberculosis (TB)

Latent Tuberculosis: Latent TB is a state of persistent immune response to stimulation by *Mycobacterium tuberculosis* antigens with no evidence of clinically active TB. Immunosuppression from any cause including prolonged steroid therapy, nephrotic syndrome, or chronic kidney disease is a potential risk factor for reactivation. The World Health Organization (WHO) recommends three



Renal injury with bacterial infections
Direct tissue invasion
Abscess
Monocyte activation
T cell, B cell
Immune complexes
Glomerulonephritis
Proinflammatory cytokines
Interstitial nephritis
Endothelial injury
Adhesion molecules/ Endothelin
Renal Ischemia
Complement
Coagulation
Hemolysis
Hypovolemia
DIC
Acute tubular necrosis

Fig. 1 Mechanisms of renal injury due to bacterial infections. (Adapted from reference [1])

Table 1 Profile of renal involvement and renal pathology findings in common bacterial tropical infections. (Adapted from reference [1])

Infection	Abnormal urine sediment	Proteinuria	AKI	CKD	Predominant renal pathological findings
Tropical bacterial infections					
Leptospirosis	++++	++++	+++	+	ATN, AIN
Tuberculosis	++	++	–	+	AIN
Scrub typhus	+	++	+	–	ATN, AIN, MPGN
Salmonellosis	+++	++++	+	–	AIN, MPGN, nephritis, and pyelonephritis
Diphtheria [4]	+	+	+	–	AIN, ATN
Cholera [5]	–	–	+	–	ATN
Tetanus [6]	+	++++	+++	–	ATN
Leprosy [7]	++	+++	+	+	ATN,MPGN,MN, amyloidosis
Syphilis [8–11]	+++		+		MN, MPGN, RPGN
Legionellosis			++		Rhabdomyolysis, AIN, ATN, proliferative glomerulonephritis

ATN: acute tubular necrosis; AIN: acute interstitial nephritis; MPGN: membranoproliferative glomerulonephritis; MN: membranous nephropathy; RPGN: rapidly progressive glomerulonephritis; +: less common; ++++: very common

tests to detect latent TB: the tuberculin skin test/ Mantoux test and two Interferon-Gamma release assays – QuantiFERON-TB Gold In-Tube and T-SPOT TB. Positive tests cannot differentiate latent TB from active TB, so an evaluation to exclude active TB is warranted prior to considering treatment. Options for treating latent TB are monotherapy with Isoniazid for 6 months in countries with high and low TB incidence or alternatively, rifampicin plus Isoniazid daily for 3 months for children and adolescents aged <15 years in countries with a high TB incidence [15].

Renal and Urinary TB: Amongst those affected with genitourinary TB, children form a very small proportion (<5%) and manifest only after the first decade of life. Genitourinary TB is classified based on the extent of anatomical involvement and spans through nondestructive forms of parenchymal TB, TB papillitis, cavernous renal TB, and urinary tract TB [16]. Reactivation of *Mycobacterium tuberculosis* primary infection, especially in an immunocompromised patient, leads to a tubercle or granuloma formation that progresses to caseating necrosis and dissemination of bacilli into the collecting system and urinary tract. Unlike other bacterial urinary tract infections, tuberculous infection of the urinary tract takes a descending route. The latent period for reactivation following a primary infection ranges from 9 to 33 years.

The most common site is unilateral kidney followed by ureter and bladder involvement [17]. Renal involvement can be in the form of localized disease or secondary to miliary TB with tubercles in the renal cortex. Granuloma formation can begin in the cortex, adjacent to glomeruli or the peritubular capillaries but are less distinct in patients with associated HIV infection or immunosuppressed patients. The renal medulla is the preferred site for colonization of *M. tuberculosis* bacteria and during reactivation can lead to granuloma formation, caseation necrosis, papillitis, and papillary necrosis. Granulomatous chronic interstitial nephritis that is composed of epithelioid macrophages, lymphocytes, and Langhans giant cells (Fig. 2) can destroy the medullary compartment. The kidney parenchyma becomes replaced by caseous necrosis leading to a "putty kidney" [18]. Rarely, renal TB can present as crescentic glomerulonephritis, membranous nephropathy, or associated with amyloidosis and chronic kidney disease [19, 20].

Lower urinary tract symptoms, constitutional symptoms, gross hematuria, recurrent urinary infections, and sterile pyuria are common manifestations of urinary TB [21]. Ureteric strictures, bladder fibrosis, and renal calcification are known consequences of tuberculosis [22, 23]. Chronic fibrosis of the bladder wall and vesicoureteral junction can lead to the classical *"thimble bladder"* appearance and *"golf hole" ureter,* respectively (Fig. 2b, c).

Diagnosis: Isolation of *M. tuberculosis* in urine samples or histopathologic evidence of TB in any relevant tissue specimen confirms the diagnosis. Radio imaging plays a critical role in the diagnosis of urinary tuberculosis. Acid-fast bacilli smear microscopy of urine has high specificity but low sensitivity [24]. Culture techniques with Mycobacteria Growth Indicator Tube (MGIT) yields high specificity with acceptable sensitivity but is time consuming. The Xpert MTB/RIF is a cartridge-based nucleic acid amplification test (NAAT) for rapid diagnosis of urine *M. tuberculosis* DNA and antibiotic sensitivity. Another rapid diagnostic test is the lateral flow assay that detects mycobacterial cell wall glycolipid lipoarabinomannan (LAM) [25, 26].

Management: The principles of management include antimycobacterial cure and preservation

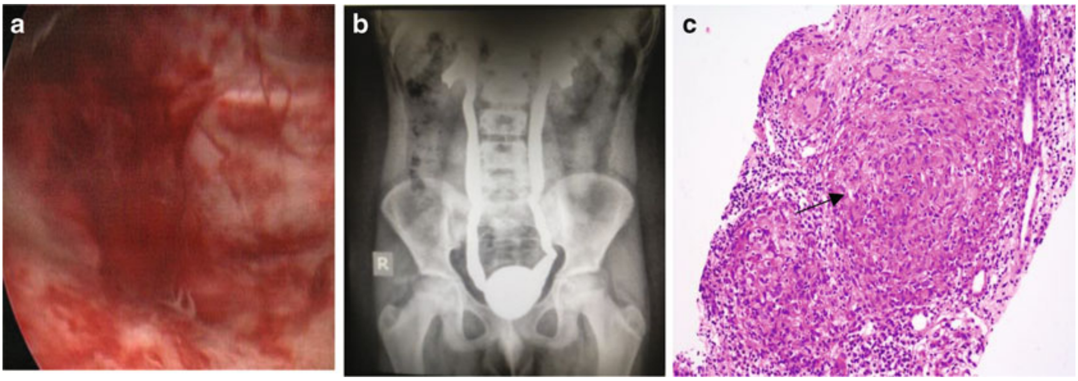


Fig. 2 (**a**) Cystitis cystica changes of the bladder wall with multiple areas of diffuse mucosal bleeding in an adolescent boy diagnosed with urinary tuberculosis. (**b**) The MCU reveals a small capacity bladder with patulous ureteric orifices (Thimble bladder) and bilateral vesicoureteral reflux. (**c**) Light microscopy of the kidney specimen showing granulomatous inflammation(black arrow) composed of epithelioid macrophages, lymphocytes, and langhans giant cells replacing a large portion of the tubulointerstitial compartment. of tissue or organ function. Anti-tuberculous treatment for newly diagnosed genitourinary TB is for 6 months duration consisting of an *intensive phase* (2 months) with Isoniazid, Rifampicin, Pyrazinamide, and Ethambutol followed by *continuous phase* (4 months) with Isoniazid and Rifampicin. In those previously treated for tuberculosis, the regimen is for 8 months with Isoniazid, Rifampicin, Pyrazinamide, Ethambutol, and Streptomycin (2 months) followed by Isoniazid, Rifampicin, Pyrazinamide, and Ethambutol (1 month) and Isoniazid, Rifampicin, and Ethambutol (5 months) [27, 28]. Guidelines on management of multidrug resistant TB, an emerging challenge, has been made available by the WHO [29].

A recent review on urogenital TB describes the approach to medical and surgical management [30]. Surgical therapies for genitourinary TB are indicated in complicated disease. Nephrectomy is indicated for nonfunctioning kidney with or without calcification and in the presence of extensive disease involving the whole kidney, in those with hypertension with ureteropelvic junction (UPJ) obstruction and pyonephrosis. Some of the reconstructive surgeries that are undertaken for complicated urinary TB are ureteroneocystostomy, stricture excision, augmentation cystoplasty, and urinary conduit diversion.

Leptospirosis

Leptospirosis is a zoonotic, waterborne disease caused by *Leptospira interrogans*, an obligate aerobic spirochete. It is a re-emerging disease, endemic to tropical and subtropical regions but unfortunately underreported and underrecognized [31]. Primary reservoirs are rodents or rats. The kidney is commonly affected in humans with leptospiral infection. Spirochetes colonize the proximal convoluted tubule and are excreted in the urine of the rat [32]. In humans, spirochetes adhere to tubular epithelium, invade the renal interstitium, and get excreted in the tubular lumen over a span of 1–2 weeks.

Risk factors for leptospirosis are related to occupational exposure, namely, agriculturists, animal caretakers, fisherman, sewage workers, mining workers, and sugarcane workers. A contaminated environment has been identified as a risk factor in urban slum populations [33, 34]. Leptospirosis can manifest as an early anicteric phase (3–7 days) with fever, headache, myalgia, nausea, vomiting, malaise, and conjunctival redness. This is followed by a temporary recovery phase that leads to the second phase (icteric phase) characterized by multiorgan involvement. Weil's disease is a severe manifestation of leptospiral infection that manifests with hepatic failure, pulmonary hemorrhage, and acute kidney injury [35].

During infection, the activated innate immune system generates an inflammatory response. The microbial Pathogen-Associated Molecular Patterns (PAMPs) get recognized by the Pattern Recognition Receptors (PRRs) expressed at the surface of Toll-like receptors (TLRs), and nucleotide-binding oligomerization domain (NOD)-like receptors (NLRs). This triggers release of pro-inflammatory cytokines such as tumor necrosis factor alpha (TNFα). An uncontrolled cytokine production could result in a cytokine storm that leads to sepsis-like syndrome with multiorgan failure. The outer membrane proteins (OMP) of *Leptospira* contain antigenic components causing tubular dysfunction and inflammation. The OMP LipL32 binds to TLR2 in proximal tubule cells activating the nuclear factor and production of iNOS and TNF-α in the proximal tubule [36–38].

The spectrum of renal involvement in leptospirosis ranges from asymptomatic urinary abnormalities of mild proteinuria and microscopic hematuria to AKI, hemolytic uremic syndrome-like disease, and CKD of unknown origin. AKI is a common complication of leptospirosis in both the icteric and anicteric phases of the disease. The prevalence of acute kidney injury is reported to be 10–60% in studies from Brazil and South Asia [39]. In hospitalized patients, leptospirosis is responsible for AKI in 0.6% of children and 45.8% of adults [40, 41]. Leptospirosis can coexist with other infections, such as scrub typhus [42], Dengue infection [43], and Hanta virus [44], that can complicate the clinical presentation and outcome.

Renal involvement in leptospirosis has been reviewed comprehensively [39, 45, 46] and acute tubulointerstitial nephritis is the most common underlying pathological lesion. The primary site of injury is the proximal convoluted tubule leading to a decrease in sodium/hydrogen exchanger isoform 3 (NH3), aquaporin 1 and 2, and Na^+ K^+ ATPase [47]. Tubulointerstitial damage is also a consequence of hemodynamic alterations, hypotension, hyperbilirubinemia, and rhabdomyolysis [32]. Glomerular lesions are rare and could manifest with mild proteinuria secondary to foot process fusion and focal swelling of the basement membrane [48]. *Leptospira* associated AKI manifests as a non-oliguric AKI accompanied by hypokalemia; tubular proteinuria; and sodium, magnesium, and phosphate wasting. However, oliguric AKI has also been reported in children [49]. Hyperkalemia may be seen with severe AKI or rhabdomyolysis and is a predictor of poor outcome [32]. AKI in the majority resolves by the second week of disease and mortality is lower in children compared to adults [50].

Diagnosis

The urinary sediment usually contains red blood cells (RBC), white blood cells, bile casts, and granular casts. Dark field microscopy of urine shows spirochetes between the first and fourth week of illness. Leptospiral organisms are fragile, which makes isolation from the blood, cerebrospinal fluid, or urine challenging. Microagglutination tests are highly sensitive and specific to detect *Leptospira*-specific antibodies. A fourfold rise in bacterial cell titer in samples collected 2 weeks apart confirms infection. In the first week of illness, rapid antibody tests using an enzyme-linked immunosorbent assay (ELISA) to detect immunoglobulin M (IgM) to leptospiral antigens are useful. The real-time quantitative Polymerase Chain Reaction (PCR) assay is a sensitive method for detection of leptospiral DNA. Several molecular methods for serotyping of leptospires are available [32, 51]. Recent reviews propose newer biomarkers for AKI in various tropical infections, including malaria, leishmaniasis, and schistosomiasis. Biomarkers for leptospiral AKI are NGAL, Syndecan-1, and ICAM-1 [52, 53].

Renal biopsy (Fig. 3) findings involve a spectrum of acute interstitial nephritis, acute tubular necrosis with bile or red blood cell casts, mesangioproliferative glomerulonephritis or focal necrotizing glomerulonephritis, and, rarely, vasculitis with focal hemorrhage [45, 54].

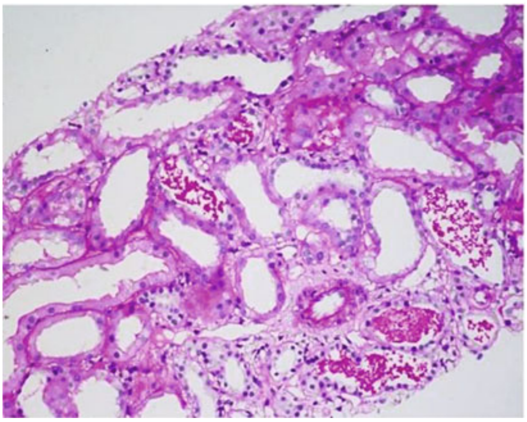

Fig. 3 Acute tubular injury due to leptospirosis. Periodic acid–Schiff (PAS), ×200. Tubular epithelial cells are attenuated and the lumen is expanded. Cell debris is seen in some of the tubules. Immunostaining for myoglobin was negative. There is interstitial edema. The glomeruli in this biopsy specimen appeared to be morphologically normal. Immunofluorescence staining for immunoglobulin (Ig)G, IgM, IgA, complement component (C) 3 (C3), C1q and kappa and lambda light chains were negative. (Images are courtesy of Dr. A Abraham, Renopath, Center for Renal and Urological Pathology Pvt., Chennai, India)

Treatment

Severe leptospirosis is treated with intravenous penicillin, ceftriaxone, or cefotaxime for 7 days. Oral antibiotics, such as doxycycline, amoxicillin, ampicillin, erythromycin, or azythromycin, are indicated in less severe disease [55]. Supportive therapy is critical in the form of fluid resuscitation, maintenance of acid–base and electrolyte balance, and respiratory support. Doxycycline in high risk individuals has been found to be effective in preventing leptospiral infection [56]. Dialysis is indicated in about 60% of adults with severe leptospiral AKI. Reduction in mortality has been observed with early daily dialysis compared to late and alternate day dialysis [45, 57]. Though hemodialysis and hemofiltration are associated with lower mortality and shorter time of recovery in adults, there is no consensus on the best modality of dialysis in children. Various modalities of dialysis, such as peritoneal dialysis, hemodialysis, and hemofiltration, have been used [45, 58]. Plasmapheresis has been found to be effective in severe forms of leptospiral AKI [59].

Outcomes: The WHO reports pediatric mortality rates due to leptospirosis of 0.22–0.32 per million age-related population, with AKI being an important predictor of poor outcome [60]. Risk factors for death include AKI, oliguria, pulmonary involvement, leukocytosis, thrombocytopenia, and electrocardiographic abnormalities [50, 61]. Leptospiral infection could lead to chronic tubulointerstitial nephritis and cause progression of kidney diseases insidiously. It has been proposed to be a risk factor for CKD of unknown origin [62, 63].

Rickettsia

Rickettsial infections are a group of zoonoses causing febrile illness in the tropics and transmitted by ticks, fleas, or mites. Fever, rash or eschar, conjunctival congestion, myalgia, hepatosplenomegaly, and systemic involvement are common manifestations [64]. Rickettsial diseases have a wide distribution and vary in severity, from self-limited infections to fulminant and often fatal illnesses. Scrub typhus, Rocky mountain spotted fever, and Q fever are important infections that involve the kidney.

The spectrum of renal pathology with rickettsial infections includes acute interstitial nephritis, acute tubular necrosis, vasculitis, rhabdomyolysis, direct invasion of tubules, and, rarely, acute glomerulonephritis [65, 66]. Scrub typhus is caused by the bacterium *Orientia tsutsugamushi* (*Rickettsia tsutsugamushi*) endemic to South Asia, and is transmitted to humans by infected Leptotrombidium mite larva. In adults, the prevalence of associated urinary abnormalities is high with 20–60% presenting with AKI, and oliguria, thrombocytopenia, and rhabdomyolysis predict AKI [67, 68]. In children, the burden of AKI secondary to scrub typhus ranges from 3% to 16%, including those from intensive care units [40, 69]. The mechanisms of AKI are attributed to direct infiltration, associated glucose-6-phosphate dehydrogenase deficiency, rhabdomyolysis, and renal ischemia leading on to ATN, interstitial nephritis (Fig. 4), and mild mesangial glomerulonephritis. Early treatment with doxycycline has been effective in clinical and renal recovery [66, 70, 71].

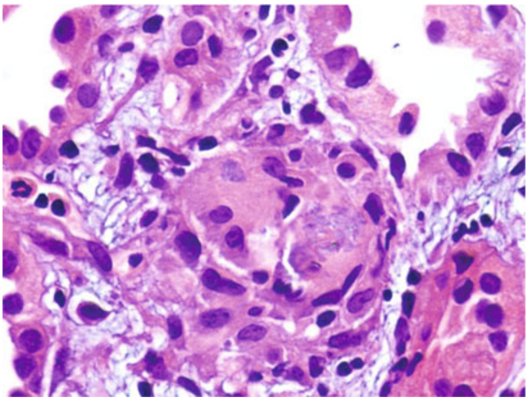

Fig. 4 Acute tubulointerstitial nephritis secondary to scrub typhus. Light microscopy shows acute tubular injury with crystal formation and edematous interstitial space in the vicinity with occasional inflammatory cells (HE stain, 40x). (Courtesy of Dr. M Vankalakunti, Pathology Lab, Manipal Hospitals, Bangalore, India)

Renal involvement in Q fever caused by *Coxiella burnetii* includes asymptomatic hematuria, proteinuria, acute tubulointerstitial nephritis, or immune-mediated glomerulonephritis [72, 73]. Nearly one-third of children with Rocky Mountain spotted fever caused by *Rickettsia rickettsii* are affected with AKI causing a higher risk of mortality [74–76]. While Weil Felix test has poor sensitivity as a diagnostic test, PCR assays are sensitive for diagnosis of rickettsial infections. Doxycycline is the drug of choice and chloramphenicol and macrolide antibiotics are alternative options. Supportive management is the mainstay of management of AKI [64].

Infection-Related Glomerulonephritis

Infection-related glomerulonephritis (IRGN) is a term used to describe glomerulonephritis that is associated with ongoing infection (syn-infectious) or that which occurs with a latent period following an infection (post-infectious GN) [77].

In the past decade, there have been several good reviews on IRGN, post-infectious glomerulonephritis (PIGN), and *Staphylococcus*-

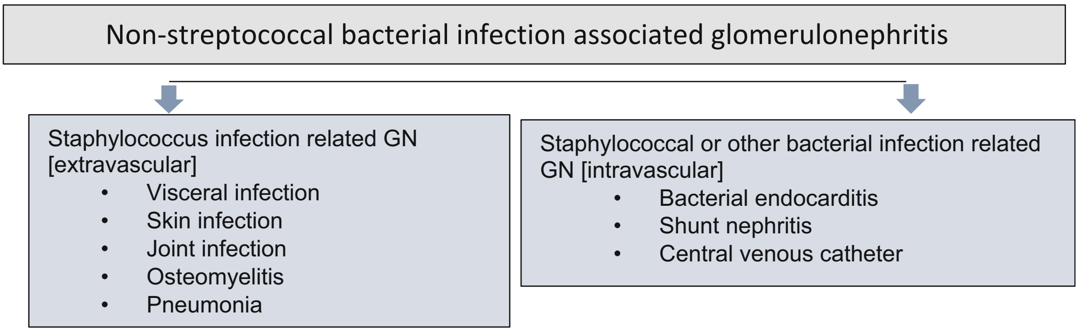
associated GN [78–81]. In this regard, the differences in the clinical presentation of IRGN between adults and children have also been highlighted [82]. Moreover, the understanding of the various mechanisms related to infections triggering glomerulonephritis has considerably improved. The proposed key mechanisms described are based on the theory that there is a hereditable genetic risk factor (first hit) that predisposes individuals to mount an altered autoimmune response. This is followed by exposure to infectious agents (second hit) that could get modified by epigenetic factors leading to activation of the innate immune system alongside the antigen-specific adaptive immune response. This in turn generates antigen-specific T cells and B cells that mediate glomerular injury through the inflammatory effector cells or complement system. Similarly, in staphylococcal associated GN, nephritogenic antigens like the super antigens of *Staphylococcus* could trigger immune complex entrapment within the glomeruli or immune complexes formation in situ against planted glomerular antigens. Additionally, the alternate/lecithin pathway and activated plasmin and complement pathways act in concert to cause tissue injury [82, 83].

Non-streptococcal bacteria-associated glomerulonephritis mainly includes staphylococcal and other bacteria-related (intravascular and extravascular) glomerulonephritis (Fig. 5). *Staphylococcus*-infection-associated glomerulonephritis (SAGN) is an entity that has emerged as one of the important causes for glomerulonephritis mainly in adults. While this specific entity is uncommon in children, staphylococcal endocarditis and shunt infection-related GN are not uncommon. From a broader perspective, it becomes important to differentiate the different types of IRGN. Key differences in the clinical features, investigations, pathology, and outcomes between PSGN and SAGN are listed in the Table 2. It also is important to differentiate IgA dominant IRGN from primary IgAN. The points in favor of the former are presence of hypocomplementemia, renal dysfunction, endocapillary proliferative GN, IgA deposits in the capillary walls, and subepithelial humps(Fig. 6).

A culture proven staphylococcal infection (Methicillin-resistant *Staphylococcus aureus* and Methicillin sensitive *S. aureus* and coagulase-negative *S. epidermidis* are the common organisms) is the definitive criteria for diagnosis. Supportive care along with antibiotic therapy forms the main stay of treatment for SAGN. Immunosuppression should be avoided as it does not have a clear benefit in these patients, and renal sequelae post recovery from infection is variable.

Glomerulonephritis Associated with Bacterial Infections: Endocarditis/Shunt Nephritis

Focal bacterial infections can involve the kidney. There has been an evolution over time in the renal involvement of systemic infections, with a change in the spectrum from streptococcal to a broader group of bacteria including staphylococcus. Besides respiratory and gastrointestinal infections, the two specific entities of focal bacterial



Non-streptococcal bacterial infection associated glomerulonephritis
Staphylococcus infection related GN [extravascular]
• Visceral infection
• Skin infection
• Joint infection
• Osteomyelitis
• Pneumonia
Staphylococcal or other bacterial infection related GN [intravascular]
• Bacterial endocarditis
• Shunt nephritis
• Central venous catheter

Fig. 5 The clinical entities associated with non-streptococcal glomerulonephritis. (Adapted from Refs. [81, 84])

Table 2 Differences between PSGN and SAGN. (Adapted from reference [77])

Parameters	PSGN	SAGN
Age	Mainly children	Mainly adults, occasionally children
Infection source	Pharyngitis, pyoderma, otitis media, tonsillitis, infected scabies	Endocarditis, skin abscess, leg ulcers, osteomyelitis, septic arthritis, pneumonia
Infection free latent period	Present	Not present
Clinical features	Hematuria, hypertension, oliguria, mild proteinuria, occasionally renal dysfunction	AKI, microscopic hematuria, nephrotic range proteinuria, occasionally leukocytoclastic vasculitis rash
Laboratory features	Low C3, normal C4	Low C3 in 30–50%, normal C4
Renal histopathology	LM: Diffuse exudative proliferative GN	LM: Mesangial hypercellularity, endocapillary proliferation in some, segmental necrotizing lesions common, acute tubular necrosis frequent
	IF:C3 with or without IgG along capillary loops and mesangium EM: Predominantly subepithelial deposits	IF: IgA dominant or codominant with C3 or exclusive C3, pauci-immune in a few. EM: Predominantly mesangial deposits
Outcomes	Usually complete recovery	Unpredictable

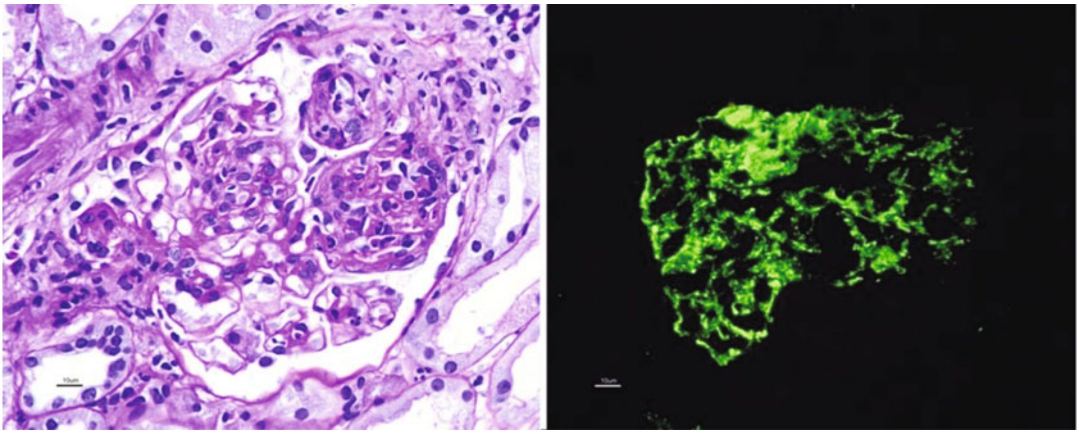


Fig. 6 Light microscopy shows global endocapillary proliferation with presence of neutrophils in the tufts. Cellular crescent is noted partially (PAS stain, 40x). Immunofluorescence shows coarse granular deposits in the mesangial region and capillary walls with IgA (3+). (Courtesy: Dr. M Vankalakunti, Nephopathologist, Manipal Hospitals, Bangalore, India)

infections causing renal injury are endocarditis and shunt nephritis.

Bacterial Endocarditis

The reported occurrence of renal lesions in patients with bacterial endocarditis is variable. Renal manifestations in patients who underwent renal biopsies ranged from 18% to 25% [85, 86]. Common bacteria causing endocarditis are *Staphylococcus*, *Streptococcus*, and *Bartonella henselae*, occasionally rickettsial infection, while culture negative endocarditis is not uncommon. Children at risk for endocarditis are those with valvular heart disease and congenital heart disease and rarely adults with vascular access-related bacteremia [87, 88].

Clearly there has been a shift in the paradigm of the pathogenesis behind renal involvement in bacterial endocarditis over time. Historical reports revealed microemboli from infected vegetations to cause renal lesions but ongoing evidence proposed immunologic mechanisms to be the pathogenic factor. However, there still prevails uncertainty in the evidence that supported immune complex mechanisms. The alternative mechanisms proposed are direct injury of endothelial cells by bacteria, trigger of antibodies against self-protein like proteinase 3 causing ANCA antibody-associated autoimmune renal injury, and abnormalities in complement regulatory proteins [89, 90].

Clinical presentation: In a cohort of 49 patients with endocarditis, including two children, the most common clinical syndromes of renal involvement were acute renal failure, acute nephritic syndrome, rapidly progressive glomerulonephritis, and nephrotic syndrome. However, severe AKI and rapidly progressing glomerulonephritis associated with bacterial endocarditis are rare entities in children [88, 91, 92]. Hematuria is seen in the majority with reduction in C3 levels seen in over 50% of patients. In a minority, low C4 and ANCA serology is positive. In recent years there has been appreciable number of case reports describing subacute bacterial endocarditis (*Streptococcus*/*Enterococcus*/*Bartonella*) associated with ANCA-PR3 positivity and pauci-immune GN [93–95].

The underlying histopathological lesions range from a spectrum of renal infarction due to septic emboli, acute interstitial nephritis, and cortical necrosis in the early reports to crescentic glomerulonephritis, diffuse proliferative glomerulonephritis, mesangial hypercellularity, and acute tubular injury with no micro-abscess or cortical necrosis among recent reports [86, 88]. C3 deposits in IF predominate followed by IgM and fewer IgG and IgA have been observed. Rarely, pauci-immune staining and full house under IF have been identified. Immunoglobulin and C3 deposits were associated with *Bartonella* and *Coxiella* infection-related endocarditis and there were no specific differences in the pathology features of streptococcal and staphylococcal endocarditis. Electron microscopy typically reveals electron dense deposits in the mesangial area and subendothelial space.

Treatment and outcomes: Treatment primarily consists on appropriate antibiotics and immunosuppression in cases of severe renal injury. Methylprednisolone, cyclophosphamide, and plasmapheresis have been used in various case reports in adult and children. In a predominant adult series, 21% deaths were observed. In those who survived, 32% had complete renal recovery and 10% went on to renal failure. Case reports of children also reveal use of aggressive immunosuppression in selected cases of severe renal dysfunction alongside antibiotics with variable outcomes of recovery or persistent renal sequelae [88, 89, 91, 92].

Shunt Nephritis

Shunt nephritis is an uncommon immune complex-mediated nephritic syndrome with or without renal dysfunction that is associated with chronically infected cerebrospinal fluid shunts. The common shunts undertaken are ventriculoatrial, ventriculoperitoneal, ventriculo-jugular, and, recently, endoscopic third ventriculostomy that have been reported across a wide range of patients from infants to the elderly. Though culture negative shunt infections are common, predominant bacteria reported to cause infections are coagulase negative *Staphylococcus* and *Propionibacterium acnes* [96, 97].

The time to develop nephritis following shunt infection is widely variable ranging from weeks to years. Pathogenesis involves formation of immune complexes triggered by the bacterial antigen that get deposited in the glomeruli and activate the complement system. Clinically patients present with fever, hematuria, hypertension, proteinuria, hepatosplenomegaly, skin rash, arthralgia, and anemia. Further, hypocomplementemia, elevated mixed cryoglobulins, and, rarely, positive ANCA have been reported [96, 98]. Histopathology reveals mesangial hypercellularity and features of membranoproliferative glomerulonephritis with mesangial deposits of IgM and C3 under IF and subendothelial deposits under EM. The treatment involves antibiotics therapy with or without shunt removal surgery. Renal recovery is associated with early and prompt removal of shunt or replacing a ventriculo-atrial shunt with a ventriculoperitoneal shunt. In the recent years there have been case reports mainly of adults highlighting the importance of early diagnosis of shunt nephritis and possible renal sequelae [97, 99, 100]. In a pooled review on the outcomes of shunt nephritis amongst 76 patients (43 children), 54% had complete renal recovery, 18% had persistent urinary abnormalities, 19% progression to renal failure, and deaths occurred in 9% [101].

Parasitic Infections

Malaria

Epidemiology

Malaria transmission occurs predominantly through the bites of female *Anopheles* mosquitoes, 30 among more than 400 different species of *Anopheles* mosquito; are the most important malaria vectors. The vector species bite between dusk and dawn. The intensity of transmission is dependent on characteristics of the parasite, the vector, the human host, and the environment. *Anopheles* mosquitoes lay their eggs in water, which hatch into larvae. Adult female mosquitoes look for a blood meal to nurture their eggs. Each species of *Anopheles* mosquito has its preferred aquatic habitat; the rainy season in tropical countries favors the formation of small water puddles, which facilitate mosquito proliferation (https://www.who.int/news-room/fact-sheets/detail/malaria, accessed on 7/20/20 and 1/2/2022).

Places where the mosquito lifespan is longer and human bites are preferred over other animals are ideal for transmission of the disease, as exemplified by Africa, responsible for approximately 90% of the world's malaria cases on account of the long lifespan and strong human-biting habit of its vector species. Climatic conditions such as rainfall patterns, temperature, and humidity also affect transmission, which may be seasonal, with the peak during and just after the rainy season. Malaria epidemics can occur secondary to climate change in areas where people have little or no immunity to malaria or when people with low immunity move into high transmission areas of malaria, to find work, or as refugees (https://www.who.int/news-room/fact-sheets/detail/malaria, accessed on 7/20/20 and 1/2/2022).

The development of human immunity to malaria depends on the length and intensity of exposure. In high transmission areas, years of exposure may lead to partial immunity in adults. Although partial immunity does not provide complete protection, it reduces the risk that malaria infection will cause severe disease. Children who are exposed to the disease very early in life and individuals of all age groups of areas with less transmission and low immunity do not benefit from partial immunity and are at risk of severe disease (https://www.who.int/news-room/fact-sheets/detail/malaria, accessed on 7/20/20 and 1/2/2022).

Human disease may be caused by five species of *Plasmodium* parasites: *Plasmodium falciparum*, *Plasmodium vivax*, *Plasmodium malariae, Plasmodium ovale*, and *Plasmodium knowlesi* [102]. *Plasmodium falciparum* is the most prevalent malaria parasite in the WHO African Region, accounting for 99.7% of estimated malaria cases in 2018, 50% of the cases in the WHO South-East Asia Region,71% cases in the WHO Eastern Mediterranean Region, and 65% cases in the WHO Western Pacific Region. Globally, 53% of the *P. vivax* burden is in the WHO South-East Asia Region, with the majority being in India (47%). *P. vivax is responsible for 75%* of the malaria cases in the WHO Region of the Americas (https://www.who.int/news-room/feature-stories/detail/world-malaria-report-2019, access on July 20, 2020 and 1/2/2022).

The life cycle of the five *Plasmodium* species is similar, except from the dormant stages of *P. ovale* and *P. vivax* [103]. After inoculation by an infectious *Anopheles* mosquito, sporozoites invade hepatocytes. After a period of 1–2 weeks of asexual replication, initially in the liver, thousands of merozoites are released into the blood per infected hepatocyte, Merozoites invade erythrocytes, where they repeat the process of asexual reproduction, the erythrocytes undergo rupture, and the newly formed merozoites continue the cycle of invasion and replication. The repeated cycles of asexual replication within erythrocytes are associated with the clinical symptoms of malaria. Some of the parasites in the blood develop into male and female gametocytes whose ingestion by a female *Anopheles* mosquito is a key step for malaria transmission.

Between 2010 and 2018 the incidence rate of malaria declined globally from 71 to 57 cases per 1000 population at risk. In 2018, most malaria cases and 94% of all malaria deaths occurred in the WHO African region. In 2018, children under 5 years of age proved to be the most vulnerable group and accounted for 67% (272,000) of all malaria deaths worldwide (https://www.who.int/news-room/feature-stories/detail/world-malaria-report-2019, access on July 20, 2020 and 1/2/2022).

Clinical Features of Malaria

Clinical disease can be classified as *uncomplicated* or *severe malaria*.

Uncomplicated Malaria

Uncomplicated malaria may be caused by any of the human infecting *Plasmodium* species. It usually presents as a nonspecific febrile illness with symptoms and/or signs of malaria and a positive parasitological test, in the absence of evidence of end organ damage. Fever, an almost universal sign of the disease, is often higher than 40 °C and associated with rigors, chills, and intense perspiration as it resolves.

Other common nonspecific initial symptoms include malaise, fatigue, headache, cough, abdominal pain, anorexia, nausea, vomiting, diarrhea, myalgia, and back pain, and their recognition as symptoms of malaria is dependent on a high index of suspicion, which is fundamental in the care of any possibly exposed individual. Hemolysis and splenic enlargement may lead to mild jaundice. Laboratory abnormalities may include mild anemia, thrombocytopenia, mild coagulopathy, elevated blood urea nitrogen, and a small creatinine elevation, not compatible with acute kidney injury criteria [103]. The current prevalence of sickle hemoglobin trait, in many tropical populations, may reflect selection for the sickle cell trait [HbAS] through a survival advantage against death from falciparum malaria. Although HbAS seems to have no effect on the prevalence of symptomless parasitemia, it may be associated with 50% protection against mild clinical malaria, 75% protection against admission to the hospital for malaria, and almost 90% protection against severe or complicated malaria. The effect of HbAS on episodes of clinical malaria was mirrored in its effect on parasite densities during such episodes [104].

Severe malaria is generally caused by adherence to capillary beds of multiple organs of erythrocytes infected by *P. falciparum*. In high-transmission areas, young children and visitors of any age from nonendemic areas present with the higher risk of developing severe falciparum malaria. A list of clinical and laboratory characteristics of severe malaria is shown in Table 3. The diagnosis of severe malaria is defined by the presence of one or more of the listed clinical and laboratory aspects, which may occur alone or in combination, and a positive malaria diagnostic test in the absence of an optional cause.

Severe malaria may present as one or more of the following syndromes [105].

1. Cerebral malaria: develops because of parasite adherence to cerebral vasculature, may present as altered mental status, coma, seizures, and evidence of increased intracranial pressure
2. Blackwater fever: an association of acute renal failure and hemoglobinuria secondary to intravascular hemolysis
3. Severe anemia: associated with high parasite burden leading to intense hemolysis of infected red blood cells and defined as hemoglobin less than 7 g/dL
4. Acute respiratory distress syndrome
5. Hyperparasitemia: defined as presence of malaria parasite infection of greater than 5% of circulating erythrocytes
6. Metabolic complications: defined by findings such as severe metabolic acidosis and life-threatening hypoglycemia

Renal Involvement in Malaria

Severe malaria can cause disease in glomeruli, tubules, and in the kidney interstitium [106].

Malarial AKI

Acute kidney injury (AKI) is a relatively frequent complication of severe malaria and may be associated with the infection by *P. falciparum, P. vivax,*

Table 3 Clinical and laboratory manifestations of severe malaria (http://www.who.int/malaria/publications/atoz/9789241549127/en)

Clinical features of severe malaria
Impaired consciousness (including unarousable coma)
Prostration, i.e., generalized weakness so that the patient is unable to sit, stand, or walk without assistance
Multiple convulsions: more than two episodes within 24 h
Deep breathing and respiratory distress (acidotic breathing)
Acute pulmonary edema and acute respiratory distress syndrome
Circulatory collapse or shock; systolic blood pressure <80 mm Hg in adults and <50 mm Hg in children
Acute kidney injury
Clinical jaundice plus evidence of other vital organ dysfunction; and
Abnormal bleeding
Laboratory and other findings
Hypoglycemia (<2.2 mmol/l or <40 mg/dl)
Metabolic acidosis (plasma bicarbonate <15 mmol/l)
Severe normocytic anemia (hemoglobin <5 g/dl, packed cell volume <15% in children; <20% in adults)
Hemoglobinuria;
Hyperlactatemia (lactate >5 mmol/l); renal impairment (serum creatinine >265 μmol/l)
Pulmonary edema (radiological).: Radiologically confirmed or oxygen saturation less than 92% on room air with a respiratory rate greater than 30/min, often with chest indrawing and crepitations on auscultation
Hyperparasitemia: *P. falciparum* or *P. knowlesi* parasitemia greater than 10% (CDC uses >5% as a cutoff)

P. malariae, and *P. ovale*. Its incidence in the pediatric population varies depending on the choice of AKI definition and the characteristics of the studied cohort [106]. Adult literature and pediatric studies describe the association of malarial AKI with increased mortality. The pathogenesis of malarial AKI is incompletely understood; the three currently accepted hypotheses favor its association with hemodynamic, immune-mediated glomerular injury, and metabolic alterations [107].

The hemodynamic hypothesis states that malarial AKI is primarily caused by hemodynamic changes secondary to adherence from parasitized erythrocytes to adjacent healthy erythrocytes, platelets, and the capillary endothelium (cytoadherence) with the formation of intravascular clusters and rosettes. At the kidney level, the infected erythrocytes may disrupt the deep vascular beds microcirculation, leading to anemia, thrombocytopenia, and impaired blood flow to the kidneys promoting tissue hypoxia. Hypovolemia secondary to insensible fluid losses caused by fever, tachypnea, low oral intake, or vomiting may add to the hemodynamic compromise resulting in acute tubular necrosis, the most frequent cause of malarial AKI [107].

Cortical necrosis, also described in malaria, characterizes a more severe kidney injury generally associated with future development of renal failure. Its predisposing factors include hypovolemia, vasoconstriction, hemolysis/hemoglobinuria, erythrocyte parasitemia, immune complexes deposition in glomeruli, microcirculation dysfunction due to cytoadherence of infected erythrocytes, and, more rarely, rhabdomyolysis [106].

Hemoglobinuria may cause direct renal tubular injury. “Blackwater fever” is a clinical syndrome that associates hemolysis-related hemoglobinuria to AKI. Erythrocyte destruction may be related to malarial infection or to antimalarial drug toxicity, especially in patients with G6PD deficiency. Rarely, myoglobinuria from associated rhabdomyolysis may affect tubular function [108]. Thrombotic microangiopathy (TMA) has been described in association with malarial AKI. It may be related to microvascular disruption by cytoadherence or it may be secondary to antimalarial drug toxicity, especially after exposure to mefloquine and quinine agents [2].

Immune dysregulation is the second proposed mechanism for malarial AKI. Peripheral blood mononuclear cells would be activated by surface antigens on host erythrocytes and parasites' cells, leading to the release of proinflammatory cytokines such as TNF-α and interleukins 1, 6, 8, and γ. Immunofluorescence might show mesangial and capillary wall deposition of immune complexes of malarial antigen, IgG, IgM, and C3. Autoantibodies such as anticardiolipin and antiphospholipid antibodies have been associated with malarial immune-mediated vascular pathology [107].

The third proposed mechanism of malarial AKI is metabolic disruption. Parasitic infection would affect the erythrocyte cell membrane and interfere with the erythrocyte magnesium-activated ATPase. Therefore, the intracellular sodium content would be reduced creating an increased calcium influx into the cell, leading to an increased red cell deformability, shortened lifespan, and an increased tendency to peripheral pooling and organ sequestration. Other potential metabolic causes of AKI in malarial infection must include renal damage from oxidative stress caused by cell-free hemoglobin, from significant hemolysis of both healthy and infected erythrocytes. Cell-free hemoglobin is a mediator of erythrocyte membrane phospholipid peroxidation leading to changes in the red cell deformability and promoting production of prostaglandin isomers (F2-IsoP and IsoFs) which act as potent renal vasoconstrictors reducing renal blood flow and renal function [107].

Another contributing factor for kidney disease in malaria may be liver dysfunction. The main described scenarios are cast nephropathy secondary to hyperbilirubinemia and hepatorenal syndrome [106, 107]. Malaria, especially in patients with repeated episodes of infection, may lead to chronic kidney disease [106].

Clinical Features of Malarial AKI

Non-oliguric AKI may develop in up to 80% of patients affected by malaria usually 3–7 days after the onset of fever. It usually improves in 17 ± 6 days. Oliguric cases may persist for weeks [2]. Lactic acidosis secondary to tissue hypoxia, hyponatremia, and hyperkalemia are rather frequent electrolyte abnormalities observed in these patients. Hyponatremia develops before the onset of oliguria due to the initial internal dilution and sodium wasting. Hyperkalemia is secondary to hemolysis, acidosis, and, rarely, rhabdomyolysis. Patients with malarial AKI may develop proteinuria due to glomerulonephritis [2, 106, 108].

Treatment of Malarial AKI

As with AKI treatment in non-malarial infection, supportive care is the basis for treatment of malarial AKI. Data from the *Fluid Expansion as Supportive Therapy (FEAST)* trial of fluid resuscitation in children with severe infection demonstrated an increase in 48 h mortality in patients who were given fluid boluses in comparison with those who were not. A subgroup analysis of children with and without malaria showed that fluid boluses were of no benefit to either group [109]. The study concluded that, unless the patient presents with significant hypotension, fluid boluses should be avoided in the treatment of malarial AKI. Continuous IV fluids may be used with careful patient monitoring for signs of fluid overload [107].

In patients with moderate-to-severe malaria, randomized control trials have demonstrated a reduction in the development of AKI with IV prostacyclin and with acetaminophen [108, 110].

The persistence of hemolytic anemia and thrombocytopenia post adequate malaria treatment demands a high index of suspicion for TMA, especially if medications such as quinine were used for treatment [2, 111].

An increased expression of KIM-1 and matrix metalloproteinase-3 (MMP-3) in tissues from autopsied patients with malaria-associated AKI has been confirmed. Chitinase-3-like 1 (CHI3L1) was associated to AKI in children with severe malaria, with evidence to its association with mortality. Initial data show that approximately 31% of patients with malaria-associated AKI had normal levels of creatinine at presentation, illustrating the importance of new AKI biomarkers [112].

Current evidence suggests that coma, evidence of metabolic alterations such as acidosis and hypoglycemia, and renal failure are the most consistent and important predictors of death in pediatric *P. falciparum* malaria [113].

Malarial Glomerular Disease

Malarial glomerulopathy occurs rather infrequently in association with *P. malariae* and *P. falciparum*. Malarial nephritides are currently understood because of endothelial damage and immune-complex deposition. The disruption of the microvasculature homeostasis by intravascular hemolysis, coagulation, and local release of inflammatory mediators may lead to glomerular endothelium activation and damage. The presence of glomerular deposits of immunoglobulins and of circulating immune complexes points to the probable involvement of humoral immunity in the development in malarial nephritis. Hyperimmunoglobulinemia and autoantibodies are frequent findings in patients with malaria. As the presence of immune complexes containing malarial antigens is demonstrated in a fraction of the glomerular immune deposits, polyclonal B-cell activation is suggested. A generalized T-cell immunosuppression secondary to the production of immunosuppressive cytokines by macrophages and/or T cells is also observed and could be important in the development of polyclonal B-cell activation [114].

Renal involvement in the course of *P. malariae* infection (quartan malaria) presents generally with nephrotic syndrome. The most frequently observed type of glomerular lesion is a membranoproliferative type of glomerulonephritis with sparse proliferation of endothelial and mesangial cells. Granular deposits of gM, IgG, and C3 are observed in mesangial and subendothelial areas by immunofluorescence. Findings of focal and segmental glomerulosclerosis and global glomerulosclerosis may be present. Chronic glomerular disease associated with *P. malariae* is usually irreversible with treatment of the infection, suggesting a role for genetic and environmental factors [114].

Diagnosis and Treatment of Malaria

The WHO recommends prompt malaria diagnosis either by microscopy or malaria rapid diagnostic test (RDT) in all patients with suspected malaria, before administration of treatment (https://www.who.int/malaria/publications/atoz/9789241549127/en, last access on 10/24/2020/).

Given potentially severe complications of malarial infection, current treatment efforts focus on prevention. There is currently no commercially available malaria vaccine. The complexity of the malaria parasite makes development of a malaria vaccine an exceedingly difficult task. Recent progress has been made with the completion of a Phase 3 trial of the RTS, S/AS01 candidate vaccine and review by the European Medicines Agency and WHO. Over 20 other vaccine constructs are currently being evaluated in clinical trials or are in advanced preclinical development (https://www.who.int/immunization/research/development/malaria/en/, accessed on 7/22/20 and 1/2/2022).

Filaria

Epidemiology

Lymphatic filariasis is a mosquito-borne neglected tropical disease that can be caused by infection from three species of nematode parasites: *Wuchereria bancrofti*, responsible for 90% of the cases, *Brugia malayi*, and, more rarely, by *Brugia timori*. It is transmitted by five genera of mosquitoes (*Culex*, *Anopheles*, *Aedes*, *Mansonia*, and *Ochlerotatus*). Adult worms dwell in the lymphatic vessels and disrupt the normal function of the lymphatic system. The worms can live for approximately 6–8 years and, during their lifetime, produce millions of microfilariae or immature larvae that circulate in the blood.

Mosquitoes are infected with microfilariae by ingesting blood when ingesting a blood meal from an infected host. Microfilariae develop into infective larvae within the mosquito. Mature parasite larvae enter the body after being deposited on the skin during the infected mosquitos' bite. The larvae migrate to the lymphatic vessels where they develop into adult worms, continuing the transmission cycle.

In 2000, the WHO launched the *Global Program to Eliminate Lymphatic Filariasis* (GPELF). WHO's strategy has focused on stopping the spread of infection through annual large-scale provision of the recommended basic package of care and vector control to all eligible people in affected areas (https://www.who.int/news-room/fact-sheets/detail/lymphatic-filariasis, last access on 10/24/2020).

Clinical Presentation and Genitourinary Involvement in Filariasis

Lymphatic filariasis infection may be asymptomatic, or present as acute or chronic conditions. The majority of infections are asymptomatic, affected individuals contribute to transmission of the parasite, without external signs of disease. When lymphatic filariasis develops into chronic conditions, it presents as lymphedema or elephantiasis of limbs and hydrocele. Breasts and genital organs are frequently involved. Chyluria and tropical pulmonary eosinophilia are less common clinical conditions. Secondary bacterial skin infections, or less frequently the death of adult worms, often complicate chronic lymphedema or elephantiasis, leading to the development of acute episodes of skin, lymph nodes, and lymphatic vessel inflammation. Hydrocele is the most common chronic clinical abnormality in men with bancroftian filariasis. It results from the accumulation of clear straw-colored fluid in the tunica vaginalis surrounding the testicles. Genital manifestations such as edema of the labia majora are uncommon in females (https://www.who.int/news-room/fact-sheets/detail/lymphatic-filariasis).

Chyluria, the presence of chyle in the urine, can be classified as either parasitic or nonparasitic. The primary cause of the parasitic form is filariasis. It is caused by rupture of dilated abdominal lymphatics into the urinary excretory system. It is generally episodic; each episode may last for days or weeks. Chyle or blood clots may cause urinary retention [115, 116]. Chyluria may be asymptomatic or present in association with dysuria, hematuria, anemia, hypoproteinemia, weight loss, malnutrition, and cachexia. Chyluric hypolipidemia may develop due to loss of lipids such as triglycerides, phospholipids, and cholesterol and deficiency of fat-soluble vitamins may occur. The differential diagnosis of chyluria includes cavitating renal tuberculosis, nephrotic syndrome, and retroperitoneal malignancies. Unlike patients with nephrotic syndrome, urinary sediment does not contain lipid-laden oval fat bodies or fatty casts but may present with large numbers of lymphocytes, consistent with the leakage of lymphatic fluid into the urine [115, 116].

Renal disease is rarely observed in patients without microfilaremia. Kidney disease can be diagnosed predominantly in areas with poor vector control and inadequate health-care facilities. Glomerular involvement shows a variety of lesions by light microscopy, including diffuse, membranoproliferative, minimal-change, chronic sclerosing glomerulonephritis, and the collapsing variant of focal segmental glomerulonephritis. Microfilariae may be found in the arterioles, glomerular and peritubular capillary lumina, tubules, and interstitium. Immune deposits containing worm antigens and structural components can be shown by immunofluorescence and electron microscopy. Proteinuria and/or hematuria has been detected in over 50% of cases with lymphatic filariasis; 25% showed glomerular proteinuria [117]. Hematuria may be caused by mechanical damage to glomeruli by circulating microfilariae or a manifestation of immune-mediated glomerulonephritis [118].

An increase or development of new onset proteinuria and worsening of kidney function can be observed following initiation of diethylcarbamazepine or ivermectin probably due to an exacerbation of the immune process secondary to antigen release into circulation after death of the parasite. The response to treatment is inconsistent in those with nephrotic syndrome; kidney function decline may continue, despite clearance of microfilariae. Therapeutic apheresis has been utilized to reduce the microfilarial load before starting diethylcarbamazepine to prevent antigen release [117].

Diagnosis

Circulating microfilariae can be detected by examining thick smears (20–60 μl) of fingerprick blood. Blood must be collected at a specific time depending on the periodicity of the microfilariae. Rapid blood antigenic and antibody diagnostic tests and microfilariae DNA detection in human blood and in mosquitoes using Polymerase Chain Reaction (PCR) have been recommended for mapping, monitoring, and transmission assessment surveys (https://www.cdc.gov/

parasites/lymphaticfilariasis/health_professionals/dxtx.html, last access 1/2/2022).

Treatment

Treatment of lymphatic filariasis is currently implemented using single-dose combination drug regimens, which generally include diethylcarbamazine (DEC). A single dose of albendazole (400 mg) with either DEC (6 mg/kg) or ivermectin (200 μg/kg) reduces microfilaria counts to very low levels for at least 24 months, in the absence of reinfection. Albendazole with DEC is believed to have better macrofilaricidal activity than albendazole with ivermectin. However, since DEC should not be used in patients with onchocerciasis, the albendazole/ivermectin regimen is preferred for treatment of lymphatic filariasis in areas that are co-endemic for onchocerciasis. Mass drug administration programs usually provide these medicines annually [115].

Onchocerca volvulus and *Loa loa*

Glomerular disease has been reported in association with two other filarial infections: *Loa loa* and *Onchocerca volvulus*

Onchocerciasis, also known as river blindness, is found in sub-Saharan Africa and sometimes in Central and South America. It is caused by a roundworm, *Onchocerca volvulus*. The main vectors for human onchocerciasis are the *Simulium* black flies. Skin involvement is common and presents as intense pruritus and inflammation resulting in papules, plaques, hyperpigmentation, and widespread lichenified onchodermatitis. Ocular involvement is also common and may result in blindness. A higher incidence of proteinuria and nephrotic syndrome, in association with *Onchocerca volvulus*, is observed in hyperendemic regions in Africa. Renal biopsy may show minimal change, mesangioproliferative, or chronic sclerosing glomerulonephritis. Onchocercal antigens as well as IgM, IgG, and C3 can be shown on immunofluorescence. Treatment with diethylcarbamazine may be effective in early glomerular lesions but usually fails to treat renal lesions in patients with nephrotic syndrome [119].

Loa loa is known as the "African eye-worm" as adult worms occasionally move across the eyes of infected individuals. Humans are infected by a vector of the genus *Chrysops*, mainly *C. silacea* and *C. dimidiate*. Loiasis only occurs in Africa, where transmission is confined to rainforest and swamp forest areas of Central and Western Africa, from western Uganda to eastern Benin. The pathogenesis of *L. loa* infection is poorly understood. Loiasis may be asymptomatic, infected individuals frequently present with hypereosinophilia and high antibody titers to filarial antigens. Angioedema and pruritus are the most common clinical manifestations. Adult worms may migrate across the eye under the bulbar conjunctiva or under the skin in otherwise asymptomatic individuals. Diethylcarbamazine is the drug of choice for loiasis when microfilaria counts are low. Ivermectin and albendazole are other therapeutic options. Several cases of membranous glomerulopathy and a single case of focal and segmental glomerulosclerosis have been reported in patients with loiasis [114].

Schistosomiasis

Epidemiology

Schistosomiasis is an acute and chronic parasitic disease caused by trematode worms of the genus *Schistosoma*. Agricultural and fishing populations, without access to safe drinking water and adequate sanitation, are particularly predisposed to this disease. At least 90% of those requiring treatment for schistosomiasis live in Africa (https://www.who.int/news-room/fact-sheets/detail/schistosomiasis, last access on 10/24/2020 and 1/2/2022).

There are two major forms of schistosomiasis – intestinal and urogenital. Intestinal schistosomiasis may be caused by *Schistosoma mansoni, Schistosoma japonicum, Schistosoma mekongi, Schistosoma guineensis*, and *Schistosoma intercalatum*, while urogenital schistosomiasis is caused by *Schistosoma haematobium* (https://www.who.int/news-room/fact-sheets/detail/schistosomiasis, last access on 10/24/2020 and 1/2/2022).

Transmission occurs when people infected by schistosomiasis contaminate freshwater sources with excreta (feces or urine) containing parasite eggs. The eggs hatch in water and contaminate an intermediary host, the freshwater snail. The snail subsequently releases larval forms of the parasite, which penetrate the human skin during contact with infested water, initiating the infection process. In the body, the larvae develop into adult schistosomes. Adult worms dwell in the blood vessels where the females release eggs. Eggs may be eliminated in the feces or urine continuing the parasite's life cycle or become trapped in body tissues, causing immune reactions and progressive damage to organs. Schistosomiasis transmission has been reported from 78 countries, 52 endemic countries with moderate-to-high transmission require preventive treatment, which is known to reduce and prevent morbidity, and should be repeated over several years. Schistosomiasis is also a travel-related disease affecting visitors of endemic locations who come in contact with infested waters (https://www.who.int/news-room/fact-sheets/detail/schistosomiasis, last access on 10/24/2020 and 1/2/2022).

Clinical Features

Exposition to infested waters may lead to a pruritic rash due to cercarial dermatitis.

Acute schistosomiasis, also known as Katayama fever, usually presents 2–8 weeks after contact with infested water. Common clinical presentation includes fever, lethargy, malaise, and myalgia. Less common symptoms include cough, headache, anorexia, urticarial or papular rash, right upper quadrant pain, bloody diarrhea as well as focal neurological signs [120].

Symptomatic chronic schistosomiasis may present months to years after primary exposure, not necessarily with a clear previous history of acute schistosomiasis. Disease onset is generally insidious and reflects the level and primary location of the infection, the immune response to the eggs and the extent of systemic involvement. *S. mansoni, S. mekongi, S. intercalatum*, and *S. japonicum* cause intestinal tract and liver disease. *S. haematobium* rarely causes intestinal or liver disease but characteristically causes urinary tract disease or genital involvement. In men, schistosomiasis can cause involvement of the epididymis, spermatic cord, testicles, and prostate [121].

Morbidity during human schistosomiasis results from chronic immune stimulation by soluble egg antigens. The chronic forms of disease are characterized by granulomatous inflammation and elevated levels of pro-inflammatory cytokines. Eosinophilia is frequently observed. Natural or post-treatment worm death may slowly induce protective resistance to reinfection, through release of immunogens, which may effectively react with antigens expressed by incoming schistosomula or lead to a decrease in worm fecundity [122].

Pediatric Schistosomiasis

Exposure to infection occurs gradually, there is a progressive increase in infection intensity and prevalence as children grow up so that practically all children living in high transmission areas will have had contact with schistosome cercariae by age one. This reality calls for the need to include pediatric schistosomiasis in national control programs for adequate planning of therapeutic options and other operational strategies implementation. In a recent study in Zimbabwean with preschool-aged children an increase in anti-parasite IgM and IgE titers was shown 6 weeks after treatment with praziquantel and was associated with resistance to reinfection, demonstrating that development of naturally acquired immunity may be accelerated by treatment [123].

Renal Involvement

The prevalence of renal involvement in schistosomiasis varies according to the study population. The incidence of all forms of glomerular involvement is estimated in 5–6% and increases to 15% in the hepatosplenic form. Glomerulonephritis is described in 10–12% in autopsy studies. Proteinuria is reported in 20% of patients with *S. mansoni* infection [124].

Schistosomal glomerulopathy is more frequently diagnosed in young male patients with hepatosplenomegaly, although it has been described in the hepato-intestinal form. It can be initially asymptomatic or open only with hypocomplementemia. Presentation with nephritic syndrome and non-nephrotic proteinuria with or without microscopic hematuria is frequent. Renal insufficiency develops rarely. Subclinical glomerulonephritis may be present in the chronic forms of schistosomiasis, but the true incidence of this complication is not known [124].

In *S. mansoni*-infected patients, circulating antigens of the adult parasite and its eggs can be found in different fluids and tissues. *Schistosoma* antigen deposits can be detected in the glomeruli of patients with focal and segmental glomerulosclerosis and mesangial proliferative glomerulonephritis. There is a strong correlation between the presence of circulating antigens and glomerular disease development [124]. A classification for schistosomal glomerulopathy has been proposed in five categories, based on histopathological findings: mesangial proliferative glomerulonephritis, membranoproliferative glomerulonephritis, focal and segmental glomerulosclerosis, exudative glomerulonephritis, and amyloidosis [125]. Patients with the mesangial proliferative form may be asymptomatic, present with minimal urinary changes, such as mild proteinuria and hematuria, or develop nephritic syndrome or renal insufficiency. Membranoproliferative glomerulonephritis is associated with hypocomplementemia, with low levels of CH50, C3, and C4, suggesting activation of the classical complement pathway. An obligatory differential diagnosis in this condition is hepatitis virus B/C-associated Membranoproliferative glomerulonephritis. Focal and segmental glomerulosclerosis (FSGS), with the same histopathological findings as described in idiopathic FSGS, is the third more common glomerulopathy in schistosomiasis. Schistosomal FSGS may originate as primary FSGS, as observed in HIV, or as secondary FSGS, due to focal scaring caused by mesangioproliferative glomerulonephritis. Membranous disease, minimal change disease, amyloidosis, and IgA nephropathy have been less frequently observed in schistosomiasis, and their pathophysiologic mechanisms are still poorly understood [124].

Coinfection with *Salmonella* may lead to new-onset or worsening of nephrotic syndrome. Treatment of coexistent *Salmonella* infection has a favorable influence on the course of the glomerular disease with improvement in serum complement levels, creatinine clearance, and proteinuria following anti-*Salmonella* therapy alone or in combination with anti-schistosomal treatment. The prognosis of schistosomal glomerulopathy varies according to the histological form of the disease: minimal change, mesangioproliferative, focal proliferative, diffuse proliferative, and endocapillary forms present relatively good prognosis, provided sustained eradication of *Schistosoma* and *Salmonella* infection can be achieved, while focal segmental glomerulosclerosis or amyloidosis usually progress to renal failure despite treatment [117].

In patients with *S. haematobium* infection, hematuria and dysuria generally occur 3 to 4 months after primary infection and may be due to inflammation and ulceration in the bladder mucosa. In endemic areas, many children present microscopic hematuria, which can later become macroscopic. Polyps, hypertrophic nodules, and eggs deposition can be observed through cystoscopy. Granulomas, fibrosis, and calcifications in the vesicle wall may lead to vesicoureteral reflux and obstructive uropathy, bladder cancer and, less frequently, renal failure [124]. Irreversibility of schistosomal renal lesions may result from delayed diagnosis. Specific antiparasitic treatment and prompt initiation in the initial phases of the disease may alter the renal disease development or progression. Patients with proliferative forms do not respond to antiparasitic treatment or to immunosuppression.

In systematic review of community-based studies describing the prevalence of proteinuria, hematuria, abnormal imaging, or kidney dysfunction among children in sub-Saharan Africa, the findings of intensity of kidney damage and frequency of abnormal imaging varied widely as shown by the reported prevalence of proteinuria 32.5% (2.2–56.0%); hematuria 31.1% (0.6–67.0%); hydronephrosis 11.3% (0.0–38.0%); hydroureter 7.5% (0.0–26.4%); and major kidney abnormalities 0.1% (0.0–0.8%). Serum creatinine was reported in 4 out of 32 evaluated studies with insufficient detail to identify the prevalence of renal dysfunction. Most of the studies were performed in *Schistosoma haematobium* endemic areas. A lower prevalence of kidney disease was observed in the few studies from non-endemic areas. The study concludes that published data on pediatric kidney disease in sub-Saharan Africa is highly variable and dependent on *S. haematobium* prevalence [126].

Diagnosis

Schistosomiasis is diagnosed by detection of parasite eggs in stool or urine specimens. Antibodies and/or antigens detected in blood or urine samples are also indications of infection.

The eggs of intestinal schistosomiasis can be detected in fecal specimens by the Kato-Katz technique, which uses methylene blue-stained cellophane soaked in glycerin or glass slides. In *S. mansoni* transmission areas, the CCA (Circulating Cathodic Antigen) test can also be used. Urogenital schistosomiasis can be diagnosed using nylon, paper, or polycarbonate filters as the standard diagnostic technique. Children with *S. haematobium* frequently have microscopic hematuria detectable by chemical reagent strips (https://www.who.int/news-room/fact-sheets/detail/schistosomiasis, last access on 10/24/2020 and 1/2/2022).

For people living in non-endemic or low-transmission areas, serological and immunological tests may be useful in confirming exposure to infection and the need for thorough examination, treatment, and follow-up (https://www.who.int/news-room/fact-sheets/detail/schistosomiasis, last access on 10/24/2020 and 1/2/2022).

Prevention and Treatment

The control of schistosomiasis is based on large-scale treatment of at-risk population groups, which includes access to safe water, improved sanitation, hygiene education, and snail control (https://www.who.int/news-room/fact-sheets/detail/schistosomiasis, last access on 10/24/2020 and 1/2/2022).

The WHO strategy for schistosomiasis control focuses on reducing disease through the large-scale periodic, targeted treatment with praziquantel (preventive chemotherapy) of affected populations. The treatment-targeted groups are school-aged children and adults at risk such as fishermen, farmers, irrigation workers, and women whose domestic tasks bring them in contact with infested water in endemic areas. In school-age children, the frequency of treatment is determined by the prevalence of infection. Treatment of preschool aged children, although also recommended, cannot be included in current large-scale treatment programs for lack of suitable formulation of praziquantel. In high-transmission areas, treatment may have to be repeated every year for several years. The impact of control interventions should be determined by close monitoring. In a few countries, where there is low transmission, the focus should be on the interruption of the transmission of the disease (https://www.who.int/news-room/fact-sheets/detail/schistosomiasis, last access on 10/24/2020 and 1/2/2022).

Leishmaniasis

Epidemiology

Leishmaniasis is caused by a protozoa parasite from more than 20 *Leishmania* species. *Leishmania* parasites are transmitted through the bites of infected female sandflies. Over 90 sandfly species are known to transmit *Leishmania* parasites. The characteristics of the parasite and sandfly species, the local ecology of the transmission sites, current and past exposure of the human population to the parasite, and human behavior determine the epidemiology of leishmaniasis, Approximately 70 animal species, including humans, are natural reservoir hosts of *Leishmania* parasites. Some of the poorest people on earth are affected by the disease, which is associated with malnutrition and its immunological consequences, poor housing, and lack of financial resources. Leishmaniasis is linked to environmental changes such as deforestation, building of dams, irrigation schemes, and urbanization. Only a small fraction of those infected by *Leishmania* parasites will develop the disease, therefore, the term leishmaniasis describes the condition of becoming sick due to a *Leishmania* infection, not to being infected with the parasite.

There are three main forms of the disease (https://www.who.int/news-room/fact-sheets/detail/leishmaniasis, access on 10/24/20 and 1/2/2022).

Visceral leishmaniasis (VL), also known as kala-azar, is fatal if left untreated, clinical presentation is characterized by irregular episodes of fever, weight loss, hepatosplenomegaly, pancitopenia, and polyclonal hypergammaglobulinemia. It remains one of the top parasitic diseases with outbreak and mortality potential. In 2018, more than 95% of new cases reported to WHO occurred in 10 countries: Brazil, China, Ethiopia, India, Iraq, Kenya, Nepal, Somalia, South Sudan, and Sudan. Cutaneous leishmaniasis (CL) is the most common form of leishmaniasis. It causes skin lesions, mainly ulcers, on exposed parts of the body, leaving lifelong scars and serious disability or stigma. In 2018, over 85% of new cases occurred in 10 countries: Afghanistan, Algeria, Bolivia, Brazil, Colombia, Iran (Islamic Republic of), Iraq, Pakistan, the Syrian Arab Republic, and Tunisia. It is estimated that between 600,000 to 1 million new cases occur worldwide annually. Mucocutaneous leishmaniasis leads to partial or complete destruction of mucous membranes of the nose, mouth, and throat. Over 90% of mucocutaneous leishmaniasis cases occur in Bolivia, Brazil, Ethiopia, and Peru.

Kidney Involvement

A recent study described 73 patients admitted with cutaneous leishmaniasis, 17 of which (23.2%) were diagnosed with acute kidney injury. The risk factors for AKI in this case series were advanced age, longer delay between symptom onset and hospital admission, and longer hospital stay. Complete renal function recovery was observed in 11 cases (64.7%) at the time of hospital discharge. Observed urinary abnormalities included proteinuria (4.1%), hematuria (4.1%), and leukocyturia (5.4%). Hypokalemia was found in 12.3% of cases. Other case series have shown urinary concentration deficit in 77% of cases and urinary acidification deficit in 40.5% patients; increased microalbuminuria was observed in 35% of patients with ACL before specific treatment, and in only 8% of patients after treatment [127].

Glomerular lesions are only observed with visceral leishmaniasis caused by *Leishmania donovani*; Cutaneous or mucocutaneous leishmaniasis are not associated with glomerular involvement. Kidney involvement in visceral leishmaniasis is usually mild and transitory; it may present as glomerular or tubular manifestations. The glomerulopathy is mainly attributed to immunocomplex deposition leading to mesangial cell proliferation, hematuria, and proteinuria. The glomerular histology may show a variety of patterns ranging from purely mesangioproliferative to membranoproliferative lesions, sometimes associated with focal and segmental collapse of capillary loops. Tubulointerstitial damage is generally present and consists of tubular degeneration and inflammatory infiltration. Amyloidosis may be a complication of this condition. Immunofluorescence may show IgG, IgM, IgA, and C3 in the mesangium and capillary loops. Electron microscopy may show irregular thickening of the glomerular basement membrane with subendothelial and subepithelial dense deposits. The association of hyperimmunoglobulinemia with high IgG levels, circulating immune complexes, and high titers of rheumatoid factor and cryoglobulin, with the presence of glomerular immunoglobulin deposition suggests the involvement of polyclonal B-cell activation and “classical” B-cell activation in the pathogenesis of leishmanial nephritis.

Tubular dysfunction associated with incomplete distal tubular acidosis, impaired renal concentration, and high urinary magnesium excretion has also been described in visceral leishmaniosis. Clinical manifestations may present as urine concentration and acidification defects, microalbuminuria, proteinuria, microscopic hematuria and leukocyturia, acute interstitial nephritis, nephritic and nephrotic syndrome, and acute renal injury. Possible causes for AKI in visceral leishmaniasis patients include drug toxicity, associated infections, hemodynamic abnormalities, and immune complex deposits. Hypokalemia, leukopenia, chills, and amphotericin B use have been described as risk factors for AKI in adults. In children, secondary infections have been considered a risk factor for AKI [127]. Other less frequent disorders have been described in visceral leishmaniasis, such as primary adrenal insufficiency and the syndrome of inappropriate ADH secretion. Electrolyte disturbances are common and include hyponatremia (94.6%), hypokalemia

(26%), hypochloremia (27.2%), hypocalcemia (32%), and hypomagnesemia (41.8%). Increased urinary excretion fraction of sodium, potassium, magnesium, chloride, calcium, inorganic phosphate, and uric acid has been frequently observed. The cure of the leishmanial infection, after specific treatment, favors a regression of the above described glomerular and tubular lesions [114, 127].

Children generally have a shorter time lag between symptom onset and beginning of treatment and a higher chance of treatment success. In a retrospective study of 146 children with visceral leishmaniasis, AKI was diagnosed in 45.9% of cases according to pRIFLE criteria. Patients in the AKI group were significantly younger and had jaundice and secondary infections more often than non-AKI patients. The AKI group had significantly lower serum sodium, potassium, and albumin levels, elevated serum globulins and a more prolonged prothrombin time. The presence of secondary infections, reduced serum albumin levels, and increased serum globulin levels were considered risk factors for AKI in the studied patients. Death, mostly caused by septic shock, occurred in four patients (3.3%), younger than 1 year of age [128].

Pentavalent antimonial drugs are one of the therapeutic choices for treatment of leishmaniosis. These recognizably nephrotoxic class of medications is rapidly excreted in the urine after a parenteral dose. Although at low doses and, for a short period of time, the renal toxicity potential is low, their use should be avoided in patients with renal dysfunction. Causes of AKI after administration of pentavalent antimonial drugs include development of a urinary concentrating defect secondary to heavy metal renal toxicity, post-therapeutic massive deposition of immune complexes secondary to *Leishmania* destruction, and, rarely, interstitial nephritis [127].

Diagnosis

In cutaneous leishmaniosis, specimen collection should prioritize cutaneous and mucosal areas with macroscopic abnormalities; diagnosis can be confirmed in biopsy specimens by molecular and traditional methods.

Bone marrow aspiration is the preferred source for diagnosis of visceral leishmaniasis. Liver, enlarged lymph nodes, and whole blood (buffy coat) are other potential sources of tissue specimens.

Multiple diagnostic approaches are recommended to maximize the likelihood of a positive *Leishmania* result. Serologic testing (rK39) is recommended for persons with suspected visceral leishmaniosis in whom definitive diagnostic tests for the parasite, such as microscopic identification, culture, and molecular tests for parasite DNA, cannot be conducted or have negative results. The sensitivity and specificity of serologic tests depend on the assay and antigens used, as well as host factors. Serologic tests cannot be used to assess the response to treatment. Antileishmanial antibodies can be detected years after clinically successful therapy in some persons. Antileishmanial antibodies should not be performed as the sole diagnostic assay. Antibodies may be undetectable or present at low levels in persons with visceral leishmaniasis who are immunocompromised because of concurrent HIV/AIDS or other reasons (https://www.cdc.gov/parasites/leishmaniasis/resources/pdf/cdc_diagnosis_guide_leishmaniasis_2016.pdf, last access 10/24/20 and 1/2/2022).

Treatment

For detailed information on treatment of the various forms of leishmaniasis consultation of specialized texts is recommended [129, 130].

Trypanosomiasis

African Trypanosomiasis, also known as sleeping sickness, is a protozoal disease caused by motile hemoflagellates of the genus *Trypanosoma. Trypanosoma brucei rhodesiense* predominates in tropical east Africa while *Trypanosoma brucei gambiense* is found in tropical west and central Africa. The disease is transmitted by the bite of tsetse flies (genus *Glossina*). *T. b. rhodesiense* causes the more acute of the two forms, leading to death within 1 year if left untreated. The clinical picture associated with *T. b. gambiense* infection is usually characterized by several intermittent periods of clinical activity alternating with latent periods that persist for several years. The clinical stages of trypanosomiasis range from the trypanosomal chancre that appears at the site of inoculation to febrile attacks, diffuse intravascular coagulation (*T. b. rhodesiense*), lymphadenopathy (*T. b. gambiense*), and eventually progressive brain dysfunction leading to sleeping sickness, cachexia, and death. Although glomerulopathy associated with *T. brucei* infection has been described in several species, human glomerular disease is limited to an occasional report, same as the association of *Trypanosoma cruzi* infection (Chagas disease or American trypanosomiasis) with nephritis [114].

Trypanosomal nephritis presents as a spectrum from purely mesangioproliferative to membranoproliferative glomerulonephritis with the presence of IgM and IgG deposits and complement components in the mesangium and along the glomerular capillary walls, by immunofluorescence. On electron microscopy, large electron-dense deposits are observed in mesangial, subendothelial, and subepithelial areas. As with the other parasite-related glomerulopathies, an important pathogenic role for immune complexes is postulated in this disease [114]. The APOL1 G2 variant has been found to be strongly associated with five- to seven-fold reduced susceptibility to infection, evidenced by in vitro lysis of *T. b. rhodesiense* by plasma containing the *APOL1* G2 allele [130].

Trichenella

Trichinellosis is a parasitic infection caused by a nematode belonging to the genus *Trichinella*. Infection occurs by ingestion of infected pork, game, or horse meat, particularly in Europe and North America. The severity of the clinical course depends on parasitic factors such as the species involved, the number of living larvae ingested, and host factors such as sex, age, ethnic group, and immune status. Most infections are asymptomatic. The acute infection is two-phased; during the enteral phase, the parasite alters intestinal function, and the *parenteral phase* is characterized by an inflammatory and allergic response to muscle invasion by the larval parasites. The clinical presentation occurs predominantly by diarrhea, myositis, fever, prostration, periorbital edema, eosinophilia, and occasionally myocarditis, pneumonitis, or encephalitis. Infection severity depends on the number of ingested larvae and on treatment delay. Death may result from congestive heart failure due to myocarditis, encephalitis, pneumonitis, hypokalemia, or adrenal gland insufficiency but is presently rare because of improved treatment options [114].

Diagnosis is based on anamnestic criteria and the presence of hypereosinophilia, increased total IgE, and elevated muscle enzyme levels. Diagnostic confirmation relies on specific serological tests (enzyme-linked immunosorbent assay and immunoblot) and/or the finding of larvae in a muscle biopsy. Mebendazole, albendazole, or thiabendazole may be used for specific treatment [131].

The seemingly rare renal manifestations may present as glomerular disease, AKI, or transient urinary sediment findings. Literature reports describe severe fatal cases accompanied by acute tubular necrosis and myoglobinuria; while in milder cases, urinary sediment abnormalities have disappeared after effective infection control. A few cases of membranoproliferative glomerulonephritis associated with trichinosis have been described in which immune complexes were seen in glomeruli [114].

Echinococcosis (Hydatid Disease)

Hydatid disease is caused by *Echinococcus granulosus*, a tape worm whose eggs are passed in stool; sheep, cattle, goats, pigs, and camels are the common intermediate hosts. Infection is frequently transmitted to humans by dogs, who as humans are definite hosts for the disease. The disease's highest incidence occurs in countries where dogs are involved with sheep and cattle raising such as the Middle East, Australia, New Zealand, South Africa, South America, and the Mediterranean area. Worm embryos developed inside the eggs are liberated within the human gut, penetrate the intestinal mucosa, and reach the portal circulation. Most larvae are filtered out by the liver and lungs, but some organisms escape to the general circulation and affect other organs such as the kidneys (2%). The surviving larvae develop into hydatid cysts, which are unilocular, in contrast to those of *Echinococcus multilocularis*, which are multilocular. These cysts may be detected by accident or because of pain or accidental rupture, which causes allergic reactions and hypotension. The cysts develop more frequently in the liver (75%) and lungs (15%). Primary or sole involvement of kidneys is rare and accounts for 1–5% of all hydatid disease in humans [114].

Renal hydatid is frequently asymptomatic or presents with unspecified signs or symptom such as: palpable mass, flank pain, hematuria, malaise, and fever and, eventually, passing of daughter vesicles that can be identified as pearly structures in urine. Diagnosis of human cystic echinococcosis (CE) can be made by ultrasound or computed tomography. Laboratory confirmation relies on serological tests or, in patients with renal cysts, on the presence of daughter vesicles in the urine seen in 10% cases. Ultrasound imaging is the basis for the WHO/IWG-E – 2010 classification system for CE, which is used to guide treatment. Computed tomogram is considered superior to other imaging modalities in observing daughter cysts, minute calcifications, intracystic gas, and for preoperative anatomical localization. The treatment is surgical as simple aspiration is associated with exceedingly high recurrence rates (90%). Active and transitional lesions should be treated with a combination of surgical intervention and medical management due to high infectivity and risk of spread. Inactive lesions should be monitored. Surgical modality includes extraperitoneal and laparoscopic partial or total nephrectomy. The extraperitoneal approach is preferred as laparoscopic nephrectomy involves risk of cyst rupture, dissemination, and incomplete removal of the hydatid cyst. Total or partial nephrectomy is recommended with cyst rupture into the collecting system or outside.

Medical management is based on albendazole (10–15 mg/kg/day in two divided doses) or mebendazole (40 mg/kg/day in three divided doses). In inoperable cases, medical management should be associated with percutaneous aspiration injection and re-aspiration (PAIR) procedure in inoperable cases. Preoperative introduction of three cycles of mebendazole or albendazole, of 4 weeks duration 2 weeks apart, makes the cysts less tense preventing spillage and anaphylaxis. A 3-month post-nephrectomy course of albendazole may prevent recurrences [132].

There are a few descriptions of hydatid disease-associated glomerulopathy whose histopathology findings range from the membranous to the membranoproliferative glomerulonephritis. Glomerular involvement in *E. multilocularis* infection has not been described [114].

Fungal Infections

Systemic fungal infection affects children, infants, and neonates with an underlying compromised immune system. From a renal perspective, children at risk include those in pediatric or neonatal intensive care units, recipients of abdominal surgery or immunosuppressive medication, and those with autoimmune diseases [134]. Fungal diseases that specifically affect children on dialysis and following transplantation are addressed in respective chapters on dialysis and transplantation.

Candida is the commonest fungal species to cause blood stream infections. Among the species, *Candida albicans* is the most common causative fungus followed by *Candida* non-albicans [*C. parapsilosis*, *C. tropicalis*, *C. guilliermondii*, and *C. glabrata*]. Delayed central venous catheter removal, acute kidney injury, and dialysis are known to be associated with mortality due to systemic candidemia in children [135, 136].

The two broad groups of patients at risk to develop fungal infections relevant to pediatric nephrology practice are those admitted to PICU and preterm neonates in NICU [137]. Invasive fungal disease in the PICU setting is seen in high risk children with central venous catheters, urinary catheters, broad spectrum antibiotics, parenteral nutrition, and those exposed to systemic steroids or immunosuppressants. Invasive candidiasis, the commonest fungal infection in the PICU setting, is associated with central venous catheters and use of vancomycin for >3 days within the preceding 2 weeks [138]. The occurrence of invasive candidiasis in neonates is based on the birth weight with an incidence of 4–16% in extremely low birth weight neonates and 2–5% in very low birth weight neonates. The most common presentation is generalized sepsis with dissemination to kidneys in 5% neonates [137]. Specific renal-related risk factors for *Candida* infection include use of broad spectrum antibiotics, steroids, central venous catheters, parenteral nutrition, and following abdominal surgery [139]. Acute kidney injury is an independent risk factor for treatment failure [136].

Candida species have the ability to both colonize and invade the urinary tract. Candiduria can be an incidental finding in patients with sepsis but may not necessarily present with symptoms pertaining to the urinary tract. *Candida* pyelonephritis can present as febrile UTI or lower urinary tract infection. Rarer presentations include emphysematous pyelonephritis, perinephric abscess, fungal balls, and papillary necrosis. Figure 7 depicts the hyphae of candida in the kidney of an immunocompromised host. Asymptomatic candiduria needs to be addressed only in those who undergo a urological procedure, those with neutropenia and in low birth weight neonates. Renal candidiasis refers to a combination of candida in the urine and imaging evidence of renal parenchymal involvement or fungal balls in the urinary tract [140]. Obstructive renal candidiasis includes fungal balls causing urinary tract obstruction with associated oliguria/anuria, hypertension, flank mass, and renal dysfunction. Ultrasonography is useful in detecting fungal balls and features of urinary tract obstruction.

Diagnosis: Presence of yeast or hyphae under a direct microscopic examination with 10% KOH–calcofluor mount from a sterile site is significant. Urine culture with >10 [12] colony forming units per ml is diagnostic. More recently, non-culture methods available for diagnosis of invasive fungal infections include galactomannan for invasive aspergillosis; IA,1,3-β-D-glucan for aspergillosis, candidemia, and *Pneumocystis jiroveci* pneumonia; mannan antigen and anti-mannan antibody assays for candidiasis; latex agglutination and enzyme immune assay (EIA) for *Cryptococcus*. However, with limited data on the utility of these tools in children, no clear recommendation for their role in diagnosis can be laid out [134, 138].

Antifungal therapy: The “Clinical practice update of antifungal prophylaxis in immunocompromised children and the Clinical practice guideline for management of candidiasis” recommend antifungal prophylaxis in preterm neonates <1000 g body weight in those neonatal intensive care units with prevalence of candida infection above 5–10%. Prophylactic Fluconazole or oral

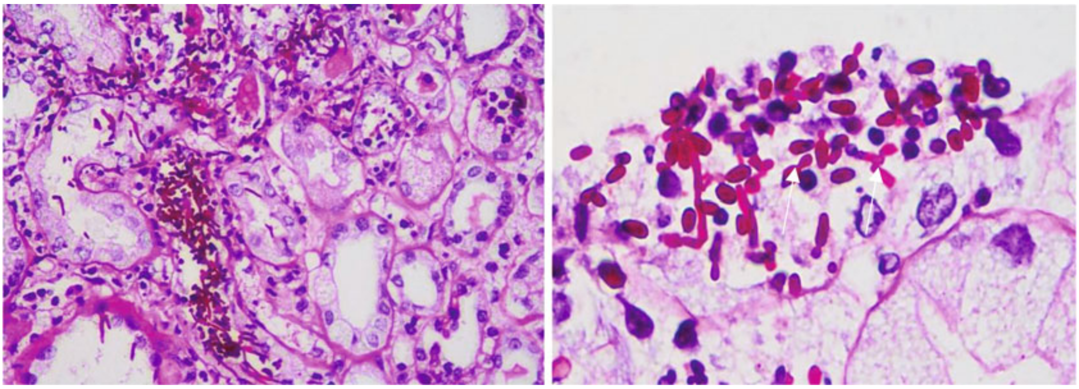

Fig. 7 (**a**) *Candida albicans* seen within the interstitium and tubular lumen PAS. (**b**) 40X magnification PAS image of budding and pseudohyphae forms (white arrows) of candida in an immunocompromised host. (Courtesy: Dr. Anila Abraham, Renopath, Centre for renal and urological pathology Pvt. Ltd. Chennai, India)

nystatin is indicated for 6 weeks. Neonatal candidiasis should be treated with Amphotericin B deoxycholate or Fluconazole for 2 weeks duration following the resolution of signs of candidemia. Lipid formulation of amphotericin B should be used with caution in the presence of urinary tract involvement and Echinocandins (Caspofungin and Micafungin) are indicated only for refractory infection. Similarly, in high risk pediatric patients with suspected invasive candidiasis, empiric treatment with echinocandins or fluconazole or lipid formulation of Amphotericin B are strongly recommended for 2 weeks duration [141, 142].

Others

Serious Forms of Urinary Tract Infection

The more serious forms of urinary tract infection include acute focal bacterial nephritis (AFBN), renal abscess, and pyonephrosis.

They are presently considered uncommon but are being increasingly reported due to improvements in the sensitivity of imaging techniques that enables their visualization. These clinical entities may be clinically similar to pyelonephritis, or may mimic abdominal inflammatory processes or tumors. The renal infectious process seems to be a continuum from pyelonephritis to abscess of ascending origin and xanthogranulomatous pyelonephritis; the different forms of clinical manifestations may be associated with urinary tract anatomy, renal vascular bed, bacterial properties, or host response to infection. Pyonephrosis should be included in the same inflammatory spectrum in obstructive or dilated collecting systems. The etiology of AFBN and of renal abscess of ascending origin is similar to that of other forms of UTI. Computed Tomography (CT) is considered to be the most sensitive and specific diagnostic method for imaging parenchymal and suppurative renal lesions. Magnetic resonance urography will possibly replace CT, as imaging methodology of choice, in the near future. Most of the described patients have pre-existing urological abnormalities, especially congenital urological malformations [143].

Acute Focal Bacterial Nephritis

Acute focal bacterial nephritis, previously known as acute lobar nephronia, is a localized, bacterial, inflammatory renal mass without liquefaction, which affects one or more renal lobules; it is regarded as an intermediary lesion between pyelonephritis and renal abscess. Characteristic CT findings are heterogeneous or wedge-shaped parenchyma with decreased enhancement. The absence of cortical rim sign can differentiate AFBN from renal infarction [142]. The administration of intravenous antimicrobial treatment until 2–3 days of fever abatement (at least 1 week) and a total treatment duration of at least 3 weeks are generally recommended in AFBN. High rates of renal scarring despite antibiotic treatment have been reported in children with AFBN [144].

Renal Abscess

Renal abscess is a focal, intrarenal (cortical) or perinephric, walled-off purulent parenchymal cavity. It is more frequently associated with an ascending urinary tract infection, although in approximately 30% of cases, it may be attributed to a hematogenous dissemination from other sites of infection such as wound infection, furuncles, or pulmonary infection. Perinephric abscesses are usually associated with a disruption of a corticomedullary intranephric renal abscess, recurrent pyelonephritis, xanthogranulomatous pyelonephritis, or an obstructing renal pelvic stone causing pyonephrosis. Gram-negative bacterial abscess commonly develops due to rupture of corticomedullary abscess while the staphylococcal infection develops due to rupture of a renal cortical abscess [145].

In children, fever and abdominal pain are the most common clinical symptoms. A previous genitourinary condition may be present in a third of patients. A positive history of previously diagnosed urinary tract infection may occur in third of the cases. Laboratory evaluation may reveal elevated C-reactive protein or erythrocyte sedimentation rate, in >80% of cases, and abnormal urinalysis in two-thirds of cases. *Escherichia coli* is the most frequently isolated microorganism and may occur in 50% cases while the isolation of

Staphylococcus aureus is less frequent ultrasound and computed tomography are the most used diagnostic imaging modalities. Treatment may be accomplished with intravenous antibiotics alone in most of the patients without the need for percutaneous drainage or surgery [146]. Antimicrobial treatment failure may be associated with large abscesses, obstructive uropathy, severe vesicoureteral reflux, diabetes, old age, and urosepsis with gas forming organisms. In the presence of a large abscess (in children >3 cm diameter) without clinical improvement after 48–72 h of adequate antibiotic therapy, a drainage procedure should be considered. The presence of obstructive uropathy indicates the need for prompt drainage, by percutaneous nephrostomy, followed by surgical correction of the primary obstructive uropathy, after the patient is stable and afebrile. Nephrectomy is indicated only for patients with diffuse damage of the renal parenchyma [145].

Xanthogranulomatous Pyelonephritis (XPN)

Xanthogranulomatous pyelonephritis (XPN) is a rare, atypical, and severe form of chronic inflammatory lesion of the kidney, whose pathomechanism is poorly understood. It is characterized by the destruction of the renal parenchyma and the presence of multinucleated giant cells and lipid-laden macrophages, as well as inflammatory infiltration and intensive renal fibrosis [146].

Pediatric XPN is rare and 60–75% of cases occur before 5 years of age. Its development is highly associated with congenital urinary tract malformations such as vesico–ureteral reflux, ureteropelvic junction obstruction, and bladder extrophy. Obstruction due to renal calculi has been reported in 38–83% of cases and 31–50% of the calculi have been of the staghorn variety. It may be related to inadequately treated chronic urinary infection by *Proteus* spp., *Escherichia coli, Pseudomonas* spp., and *Klebsiella* spp., lipid metabolism disorders, and altered immune response. Other possible etiological factors may include a lymphatic obstruction, malnutrition, arterial insufficiency, venous occlusion and hemorrhage, and necrosis of pericaliceal fat [146]. Two forms of XPN have been described: a diffuse form, which occurs in about 75% or 90% of cases, and a focal or pseudo-tumoral form, which although less frequent in general, is more commonly described in children (Fig. 8). The diffuse form is characterized by enlargement of the involved kidney with maintenance of its reniform shape, in association with nephrolithiasis, hydronephrosis, and loss and replacement of the normal corticomedullary junction by yellow masses extending to the renal pelvis and perirenal fat. The focal form is generally unilateral, confined to a renal segment or one pole of a duplex system, more frequently affecting the lower pole of the kidney. Bilateral XPN is extremely rare [146].

Clinical presentation is usually subacute or chronic with nonspecific symptoms such as loin or flank pain, intermittent fever associated with anorexia, asthenia, a palpable flank or abdominal mass, and malaise with weight loss. Acute fever and flank tenderness are most common in the diffuse forms. Urinary symptoms such as dysuria are uncommon. Laboratory results show a microcytic anemia, an elevated erythrocyte sedimentation rate, leukocytosis, thrombocytosis, and increased C-reactive protein in most patients. Urinalysis may show pyuria, hematuria, or proteinuria. Positive urine cultures are predictive for XPN but occur in only 70% of all patients. The most frequently isolated organisms are *Escherichia coli* and *Proteus mirabilis* [146].

Diagnostic imaging of diffuse XPN is based on computed tomography, which typically shows global renal enlargement with multiple low-attenuation rounded areas replacing the renal parenchyma, which represent dilated calyces or focal areas of destruction filled with pus or debris and have been named the “bear paw sign.” After intravenous contrast, an enhancement of these cavities’ walls, due to vascular granulation tissue, can be demonstrated The renal pelvis is usually contracted around a central calculus, although multiple and diffuse renal calculi may be found inside different calyces. Diagnosis of XPN may be inferred by the presence of a lipomatous component. Extrarenal disease may involve the perinephric and paranephric spaces, the posterior abdominal wall, or psoas

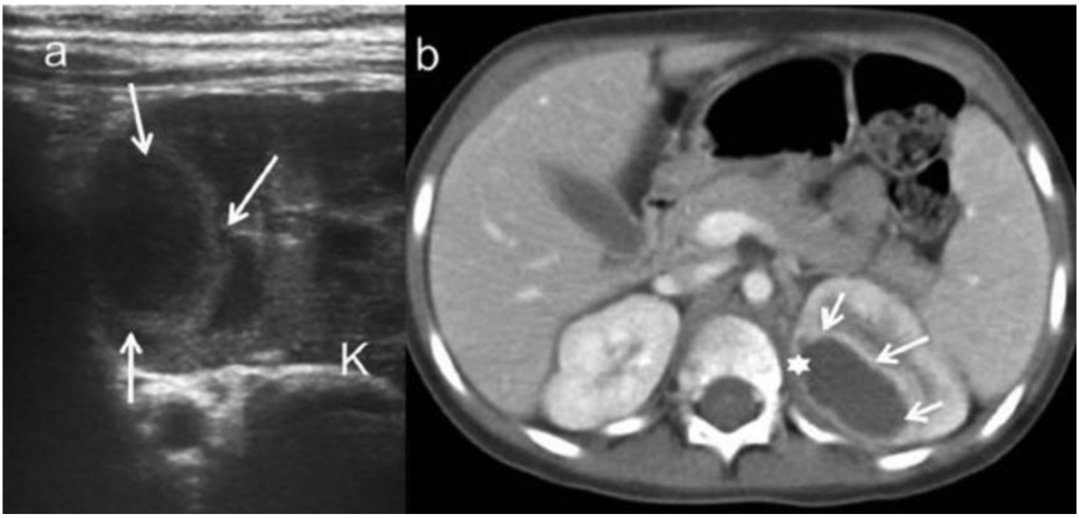

Fig. 8 Longitudinal sonographic image shows well-defined (white arrows) mass in upper pole of left kidney (K). (**b**) Contrast-enhanced nephrogenic phase transverse CT image shows hypodense lesion (asterisk) with rim enhancement (white arrows) [146]

muscle. Adenopathies are frequently present. MRI findings in diffuse XPN are variable, probably because the signal intensity of the solid component of XPN on T1-weighted images depends on the amount of xanthoma cells involved in the granulomatous process. Dimercaptosuccinic acid (DMSA) scintigraphy is helpful for the diagnosis of a non-functioning or very low renal functioning kidney. The definitive diagnosis is based on pathological findings after nephrectomy, which demonstrates areas of parenchymal destruction and necrosis as well as interstitial fibrosis and chronic inflammatory infiltrate composed of plasma cells, lymphocytes, and numerous lipid-laden macrophages. The absence of clear guidelines on the management of XPN obliges consideration of conservative and surgical treatments for each individual case [146].

Abstract

Viral infections are associated with a number of renal diseases in children resulting in significant morbidity and mortality worldwide. The role of viral infections in the pathogenesis of kidney disease has been largely based on clinical and histologic kidney findings in temporal association with a systemic viral infection and the demonstration of kidney cells infected with viral particles. Viral infections associated with productive viral replication in the kidney of immunocompromised hosts are of particular concern for children. Here, we will discuss the epidemiology, pathogenesis, outcomes, and treatment of the most relevant kidney diseases associated with viral infections in children, excluding those occurring in kidney transplant recipients, which are discussed elsewhere in this textbook (see chap. 84, Renal transplantation: infectious complications). Well-defined associations between a viral infection and kidney disease have been made for the hepatitis B virus (HBV), hepatitis C virus (HCV), human immunodeficiency virus (HIV-1), hantaviruses, and the new coronavirus SARS-CoV-2. In children with immunodeficiency states, herpes viruses, polyomavirus, and adenovirus have been recognized to induce kidney diseases. The roles of other viruses in the pathogenesis of kidney diseases are not clearly defined and remain speculative. With increasing application of molecular techniques, the understanding of the role of viruses in the pathogenesis of kidney diseases is expected to increase. In addition, more specific antiviral treatments and vaccines are currently under development and are expected to improve the outcome of viral-mediated kidney diseases in children.

Viruses

Viruses are the smallest and simplest living organisms ranging in size from 20 nm to 300 nm. They can multiply only inside living cells and require a host cell to survive. A virion usually consists of a nucleic acid core (DNA or RNA, but never both), an outer protein coating or capsid, and sometimes and outer envelope made of protein and phospholipid membranes derived at least partially from the host cell. Viruses can be classified based on their shape in four groups: filamentous, isometric or icosahedral, enveloped, and with head and tail. In addition, they have been classified into seven types based on their unique replication strategy [1]. In this chapter, we will discuss several types of viruses that cause renal diseases. These include Class I or double-stranded DNA viruses (herpes viruses, BKV, adenovirus), Class II or single-stranded DNA viruses (Parvovirus B 19), and Class IV or single-stranded positive sense RNA viruses (Hepatitis C, SARC-CoV-2); positive-sense viral RNA, like mRNA, can be directly accessed by host ribosomes and immediately translated into proteins. Other viruses discussed include Class IV, single-stranded negative sense RNA viruses (Ebola, Hantavirus, other viruses that cause hemorrhagic fevers). In these latter viruses, the negative-sense viral RNA cannot be directly accessed by host ribosomes to form proteins, and needs to be transcribed into positive-sense RNA. Other viruses discussed are Class VI or positive sense single-stranded RNA viruses that replicate through DNA intermediates (HIV-1 and other retroviruses). Finally, class VII or double-stranded DNA viruses that replicate through a single-stranded RNA intermediate (HBV) will be discussed.

The first step in viral replication is the attachment of the virus to specific host cell surface receptors. This step is followed by the viral entry step into the cells, usually involving receptor mediated endocytosis. Once inside the cells, the virus is uncoated to release its viral nucleic acids. Thereafter, viral DNA or RNA replication occurs, when the machinery to produce cellular protein of the host cells is used to produce viral proteins. Crossing the nuclear membrane is a critical barrier that some viruses must face to replicate. Viruses that cannot cross the nuclear membrane (e.g., parvovirus B19) can replicate only in actively dividing cells, when the nuclear membrane breaks down during mitosis. Finally, viral proteins are assembled in the nucleus or cytoplasm, depending on the type of DNA or RNA virus, and packaged into virions before they are released from the cells by either budding or lysis. In budding, the mechanism used by HIV-1, the virus incorporates some of the host's cell membrane as it leaves and preserves the cell.

Viruses are continuously evolving and have developed several mechanisms to survive in host cells [2]. They can undergo mutations in different viral sites to avoid recognition by the host's immune system. In order to replicate, the RNA viruses must encode RNA polymerase enzymes that are needed to convert RNA into DNA which are not present in the host's cells. These RNA polymerases make more copying errors than the DNA polymerases encoded by the DNA viruses, leading to frequent mistakes during transcription. Therefore, RNA viruses undergo more frequent mutations and can change and adapt more rapidly to survive in their host cells. Viruses, may also become latent or silent inside the cells, or produce viral proteins capable of impairing the host's immune response. The cytomegalovirus (CMV) modulates the expression of MHCI and II cell surface molecules, and the HCV virus blocks a key innate immune response in the interferon pathway that protects against viral infections. Finally, other viruses modify the function of cytokines and chemokines by producing viral homologues of these key host proteins.

Viral Infections and Kidney Diseases

Several viruses discussed above can induce kidney injury directly or indirectly by affecting specific glomerular and tubulointerstitial compartments. Table 1 shows that different viruses can cause either similar or different kidney pathologic phenotypes [3]. However, establishing causality of the kidney disease with a specific virus requires definitive diagnostic evidence of viral infection along with renal histological features consistent with the damage caused by the virus in infected cells. Infection of kidney cells can be documented by detecting viral antigens by immunohistochemistry, viral DNA or RNA by the polymerase chain reaction (PCR), and/or viral particles by electron microscopy or cultures. A common virus capable of infecting tubular epithelial cells is BKV, which causes a tubulo-interstitial nephritis (TIN) mimicking an acute rejection episode in renal transplant recipients [4]. Latent BKV infection is widespread in the general population, and reactivation of latent BKV in immunosuppressed patients can lead to TIN in these patients. Adenovirus infections can cause severe necrotizing granulomatous TIN with granulomas surrounding severely injured and virally infected distal tubules characteristic of this infection. CMV can rarely cause patchy TIN with lymphocytes, plasma cells, and macrophages. In CMV-induced tubulitis, epithelial cells, and endothelial cells can show the characteristic intranuclear glassy-appearing basophilic inclusions with a surrounding halo ("owl's eye-type" inclusion), and a marked increase in size (cytomegaly). Specific diagnosis is confirmed by immunohistochemical staining for CMV.

Viruses can also cause renal injury by increasing the recruitment of inflammatory cells, by facilitating the formation and deposition of immune complexes containing viral antigens, and/or by

inducing autoantibodies against intrinsic renal antigens due to molecular mimicry [5, 6]. Viral particles may become trapped in the glomerular filtration membrane, leading to in situ immune-complex (IC) formation, or act as an antigenic stimulus to induce autoimmunity against cross-reactive glomerular cell epitopes [7]. In addition, direct infection of renal cells may either modify a tissue antigen or a cellular immune response to evoke autoimmunity [8]. Endothelial cells are especially susceptible to the pathogenic effects of several viruses, since they carry a vast array of molecules that modulate the adhesion of leukocytes and platelets, and/or cause complement activation. Maintaining intact endothelium is essential for the normal function of the glomerular filtration barrier, and to prevent thrombotic microangiopathic lesions. Viral pathogens frequently induce the activation of endothelial cells through cytokines and leukocytes, and may disrupt the integrity of renal vessels causing vascular leakage or bleeding. Endothelial injury is implicated in the pathogenesis of viral hemorrhagic diseases, including dengue, hantaviruses, and arenaviruses [9, 10]. Activation of complement and coagulation cascades is associated with clinical symptoms consistent with hemolytic uremic syndrome (HUS) in patients with COVID19 [11].

Specific Viral Kidney Diseases

Parvovirus B19 (PVB19)

Epidemiology

PVB19 is a small, non-enveloped, single-stranded DNA virus with humans being the only host. Infections with PVB19 are very common, occur worldwide, and can cause fifth disease in children. Viral acquisition often occurs during childhood although it does occur at lower rate throughout adulthood; 70–85% adults show serologic evidence of past infection. Infectivity varies by season and is more common in winter and spring. Transmission of infection usually occurs by inhalation of virus in aerosol droplets. PVB19 can be transmitted vertically from mother to fetus and less commonly through transfusion of blood products, bone marrow, and solid-organ transplants [12].

Pathology

Various renal pathologies described in association with PVB19 include acute proliferative glomerulonephritis, collapsing glomerulopathy (CG)

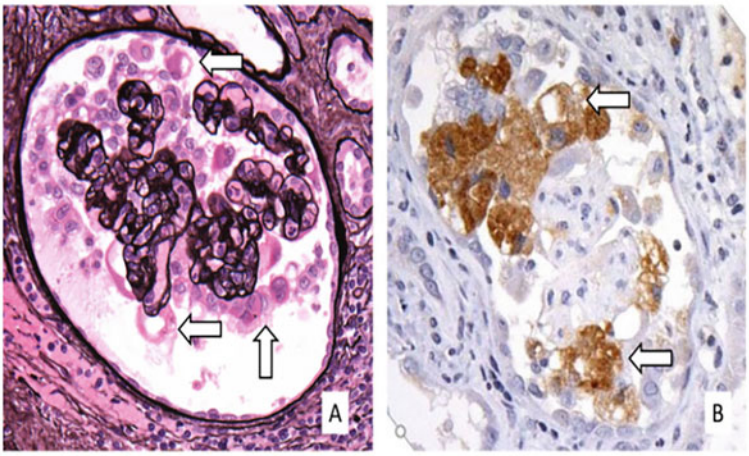

Fig. 1 Parvovirus B19 infection. (A) Collapsing glomerulopathy with hypertrophic and hyperplastic epithelial cells (arrows) and capillary luminal obliteration due to collapse (Jones Silver stain x160 magnification). (B) Immunohistochemistry stain for parvovirus B19 showing infected hyperplastic and hypertrophic glomerular epithelial cells (arrows) (x160 magnification). Courtesy: Dr. Cynthia Nast, Cedars-Sinai Medical Center, LA, CA

(Fig. 1A), focal and segmental glomerulosclerosis (FSGS), thrombotic microangiopathy (TMA), and necrotizing renal vasculitis in association with systemic vasculitis including Henoch Schonlein purpura (HSP), polyarteritis nodosa (PN) and Wegener's granulomatosis [13–15]. CG has been also described in renal transplant recipients infected with PVB19 [16]. Viral genome components have been detected in renal biopsies by PCR, and B19 antigen has been observed in the glomeruli by immunohistochemistry [17].

Pathogenesis

PVB19 has been implicated in the pathogenesis of several renal lesions, but its role in the pathogenesis is associative and speculative rather than causative. The role of PVB19 in CG has been suggested based on the higher prevalence of PVB19 DNA by PCR and in situ hybridization in renal biopsies of patients with CG as compared to other nephropathies (Fig. 1) [17]. However, it is unclear if the presence of the virus is pathogenic. PVB19 DNA has been localized to the glomerular podocytes and parietal epithelial cells, both of which have been implicated in the pathogenesis of CG (Fig. 1B). NS1, a viral protein of PVB19, has been shown to be cytotoxic in some non-renal cells [18]. It is not known whether this protein is injurious to kidney cells, but it cannot be excluded as a possible mechanism of glomerular injury.

Presentation

Acute onset of glomerulonephritis (hematuria, proteinuria, or hypertension) or rarely nephrotic syndrome (NS) after onset of PVB19 infection has been described in normal hosts, those with sickle cell disease, and rarely in renal transplant recipients [11–15].

Management

Treatment is mostly supportive but intravenous immunoglobulin (IVIG) therapy may be helpful [16].

Herpes Viruses

The structure of herpes viruses consists of a double-stranded linear DNA genome enclosed within an icosahedral protein capsid, and surrounded by a lipid bilayer envelope membrane. Eight herpes viruses infect mainly humans. These include human herpes simplex virus type 1 (oral herpes);

herpes virus simplex virus type 2 (genital herpes), varicella zoster virus (VZV), CMV, Epstein Barr virus (EBV), human herpes virus (HHV) 6 (cause of sixth disease), HHV 7, and HHV 8 (Kaposi's sarcoma herpesvirus). All these viruses can be reactivated in immunocompromised patients including those with kidney transplants. In addition, cases of IgA nephropathy, membranoproliferative glomerulonephritis (MPGN), and membranous nephropathy (MN) have been associated with herpes viruses, although little evidence has supported causality, with some exceptions. For example, while the association of varicella with nephritis has been known for decades, varicella only rarely causes fulminant renal disease in immunocompromised patients. Conversely, infectious mononucleosis, induced by the Epstein Barr virus, can cause transient hematuria and mild proteinuria for a few weeks [19]. More severe renal involvement with EBV is unusual, except for severe cases with hepatic failure, thrombocytopenia, and/or encephalitis, which can be associated with interstitial nephritis and acute kidney injury (AKI).

Cytomegalovirus (CMV)

Epidemiology

CMV is a member of the herpesvirus family. Prevalence of seropositivity increases with age and ~ 50% of people become seropositive by mid-adulthood in the United States [20]. Outside of the Unites States, the CMV seroprevalence rates run between 30% and 97% [21]. Virus transmission can occur by exposure to infected body fluids such as human milk, saliva, urine, blood and by organ transplantation. Primary CMV infection may be asymptomatic or may manifest as a self-limited febrile illness in immunocompetent individuals. After primary infection, CMV persists as a latent virus, which serves as reservoir for reactivation and transmission to susceptible individuals, such as infants and solid organ transplant recipients.

Pathology

CMV infection can cause both tubular and glomerular lesions. TIN can occur in native kidneys in congenital CMV infection and in renal allografts (Fig. 2A, B). Glomerular lesions associated with CMV infection include acute proliferative GN or severe glomerulonephritis with crescent formation [24]. Rarely, CMV can also cause CG in grafts from donors with APOL1 mutations [4, 22]. CMV is also known to cause chronic vascular injury. Cytopathic changes caused by CMV are characterized by intranuclear and cytoplasmic viral inclusions. Often, nuclei show an "owl's eye" appearance or sometimes appear smudgy. CMV infection can be diagnosed by immunocytochemical staining to detect CMV antigens. Electron microscopy can demonstrate viral particles measuring about 150 nm, often having a central electron-dense core and envelope in tubular cells and appearing as viral immune deposits in glomerular cells [23].

Pathogenesis

CMV infection can directly cause damage to tubular epithelial cells, glomerular and vascular endothelial cells, and mononuclear cells. Immune-complex GN has been documented with mesangial deposits of IgG, IgA, C3, and CMV antigens within glomeruli.

Presentation

Infection with CMV is usually asymptomatic in most patients except in those infected congenitally or that are immunocompromised. CMV positive donor/CMV negative transplant recipients have the highest reported rates of both CMV infection and CMV disease in the first 3 months after organ transplantation, although both can occur later [18]. Patients who are CMV seropositive at the time of transplantation are also at risk of reactivation and superinfection. The laboratory methods to identify a CMV infection include antigen detection, quantitative nucleic acid amplification testing (qNAT) by PCR, histopathology, and culture [18]. qNAT testing is the preferred method for routine CMV monitoring and diagnosis after transplantation.

Management

Antiviral prophylaxis and preemptive therapy are the mainstay therapies for CMV prevention.

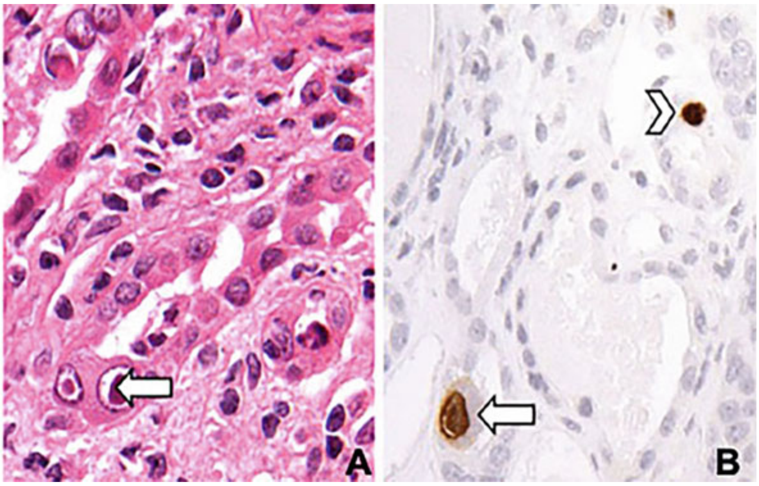

Fig. 2 CMV infection. (A) Enlarged tubular cell nucleus with a large purple intranuclear inclusion (arrow) with a smaller inclusion in the cell to the left (cytopathic change). Note the sloughed degenerated cells in the tubular lumens (H&E x240 magnification). (B) Immunohistochemistry stain for CMV showing an infected tubular cell nucleus (arrow). An infected tubular cell that has sloughed into a tubular lumen is also present (chevron) (x240 magnification). Courtesy: Dr. Cynthia Nast, Cedars-Sinai Medical Center, LA, CA

Antiviral agents shown to be effective against CMV include ganciclovir, valganciclovir, foscarnet, and cidofovir. Oral valganciclovir is recommended for CMV prophylaxis in the post-transplant period. Duration of chemoprophylaxis is dependent on the serostatus of the donor and recipient. Intravenous ganciclovir or oral valganciclovir can be used to treat CMV disease depending upon the severity of disease [18]. Major limitations of ganciclovir therapy include bone marrow toxicity and renal tubular dysfunction. Dosage adjustment is needed in the presence of renal dysfunction. Use of other antiviral agents such as foscarnet and cidofovir is often limited because of nephrotoxicity. The role of CMV immunoglobulin therapy in reducing severe CMV-associated disease after solid organ transplantation remains unclear [18].

Adenovirus

Epidemiology

Adenoviruses (ADV) are medium sized (90–100 nm), non-enveloped icosahedral viruses with double-stranded DNA. ADV infections are endemic in pediatric populations and people living in close quarters (college students and military recruits). The true incidence of ADV infection is not clear. ADV infection is asymptomatic in the normal host, but may cause hemorrhagic cystitis and or TIN in immunocompromised children, including bone marrow transplant recipients, those receiving intensive chemotherapy or rarely those that are kidney transplant recipients. Severity of disease and symptoms vary and are dependent on the serological subtypes of ADV, patient age, type of underlying immunosuppression and type of tissue/organ transplant. ADV infections are most often caused by subgroup B, serotypes 7, 11, 34, and 35. Serotypes 11, 34, and 35 are associated with hemorrhagic cystitis and severe interstitial nephritis. Recombinant adenoviral vectors are also used as a gene transfer tool. These vectors are generated by replacing the E1 gene, which is essential for viral replication, with the transgene of interest and an enhancer promoter element. Human kidney epithelial, mesangial, and endothelial cells can all be transduced successfully with these vectors [24], further supporting the notion that ADV can directly infect intrinsic renal cells. Modified human and monkey adenoviral vectors are currently being used to generate vaccines against COVID-19.

Pathology

Most ADV require the Coxsackie-virus B adenovirus receptor (CAR) to infect renal epithelial cells. ADV bind to this primary receptor and enter cells via endocytosis or micropinocytosis. Renal manifestations include features of TIN, with severe cases showing extensive tubular necrosis and destruction and rupture of tubular basement membranes and focal interstitial hemorrhage. The interstitial inflammatory response may sometimes be nodular and/or granulomatous [25].

Presentation

ADV infections manifest variably, ranging from asymptomatic infections to severe, prolonged, disseminated disease with significant morbidity, mortality and/or allograft loss. ADV are a major cause of hemorrhagic cystitis, which is more common in boys than girls with longer periods of microscopic hematuria, dysuria, and frequency in the former [19]. Renal manifestations of ADV infections include hematuria, proteinuria, and increases in serum creatinine levels. Diagnosis can be confirmed by immunohistochemistry or by electron microscopy. Additionally, ADV can be detected in the blood and urine by qNAT testing or by culture.

Management

Reduction of immunosuppression should be the initial approach in the treatment of adenovirus infections in transplant patients. Cidofovir should be considered as the next line treatment for ADV-associated disease. Patients given cidofovir should be well hydrated and probenecid can be administered to minimize the risk of nephrotoxicity. The ideal dose and frequency of cidofovir administration is not known, although dosing adjustments are needed for renal insufficiency [26].

BK-Virus (BKV)

Epidemiology

BKV is a non-enveloped, icosahedral encapsulated circle double stranded DNA virus. BKV infection is widespread and is typically acquired in childhood [27]. Approximately 80% of the population is seropositive for BKV by adulthood. Following primary infection, BKV frequently establishes latent infection in renal tubular cells and urinary tract epithelia [28]. Viral replication can occur under immunosuppression. BKV infection causes kidney disease only in immunocompromised hosts, most often in renal allograft recipients and rarely in other organ transplants. The estimated prevalence of BK-associated nephropathy (BKN) ranges from 1–5.5% [29]. Risk factors for infection include intense immunosuppression, higher degree of HLA mismatch and ureteral stent placement.

Pathology

The re-activation of silent BKV infections in immunosuppressed patients plays a critical role in the pathogenesis of BKV viruses. The specific mechanisms of viral activation remain unknown; most believe that tubular cells infected with BKV elicit an inflammatory reaction that is mediated by lymphocytes and monocytes/macrophages and that is centered around tubules which may develop large intranuclear inclusions with a cytopathic effect. BKV causes direct damage to renal epithelial and urothelial cells. Morphologic features of BKN include characteristic findings of TIN with mixed inflammatory infiltrates (lymphocytes, monocytes, and plasma cells) and tubular epithelial cells with viral intranuclear inclusions (Fig. 3A). Presence of large numbers of plasma cells within inflammatory infiltrates is consistent with an active polyoma virus infection. In addition, the humoral response can lead to immune complex deposition in tubular basement membranes. The diagnosis of BKN can be confirmed by immunohistochemistry (Fig. 3B), in situ hybridization or electron microscopy showing characteristic viral particles of about 30–40 nm in diameter.

Presentation

BKV in immunocompetent hosts are usually asymptomatic. Sometimes, healthy children can experience mild fever, malaise, vomiting, respiratory illness, pericarditis, and transient hepatic dysfunction. Most often, BKV infection is asymptomatic in renal transplant recipients and is

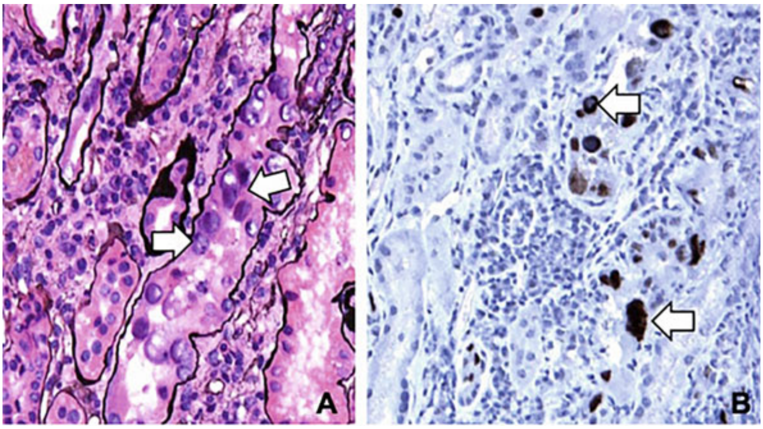

Fig. 3 Polyoma (BK) virus nephropathy. (B) Immunohistochemistry for polyoma virus (SV40 antigen) showing positive staining within enlarged tubular cell nuclei (arrows) (x160 magnification). Courtesy: Dr. Cynthia Nast, Cedars-Sinai Medical Center, LA, CA

discovered during routine monitoring by qNAT testing which has become the standard of care and recommended by the Kidney Disease: Improving Global Outcomes (KDIGO) group. BK nephropathy usually presents as renal allograft dysfunction and rarely with proteinuria and hematuria. BKV infection can rarely cause ureteral stenosis and hydronephrosis [30].

Management

Reducing immunosuppression may be helpful in clearing the infection. Role of other therapies such as leflunomide, ciprofloxacin, cidofovir, and IVIG is less well established [31].

Coronavirus

Coronaviruses are enveloped, single-stranded RNA viruses. Most coronaviruses cause mild respiratory infections without renal involvement [32]. However, in the last 20 years, three potentially lethal coronaviruses had emerged that induce a severe acute respiratory syndrome (SARS) with multiorgan involvement and kidney complications. The first potentially lethal coronavirus emerged in South China in 2002, and was named SARS-coronavirus (SARS-CoV) [33]. Patients developed severe pneumonia with diffuse alveolar damage and hypoxemia. Kidney complications were seen in the most severe cases with multiorgan involvement [34]. SARS-CoV enters cells via angiotensin converting enzyme 2 (ACE2) which is expressed in several renal cell types [35], thus explaining the renal tropism of this virus. The second virus emerged as an outbreak in the Middle East in 2012, and was named Middle East Respiratory Syndrome-coronavirus (MERS-CoV). This virus causes similar symptoms than SARS-CoV but resulted in higher mortality rates (~40%) and more kidney complications. The renal complications were attributed to both the multisystemic involvement and renal tropism of the virus [36]. The third potentially lethal coronavirus, SARS-CoV2, emerged in Wuhan, China in December 2019, and caused a major global pandemic of a severe respiratory illness named COVID-19 (coronavirus disease 2019).

COVID-19

Epidemiology

SARS-CoV2 is an enveloped positive sense-single stranded RNA virus that causes COVID-19. The incubation period is up to 14 days, with most infected individuals having symptoms around 4–5 days after exposure; however, case reports with longer incubation periods (up to 27 days) have been reported [37]. SARS-CoV2 tends to cause more serious disease in older adults and those with underlying co-morbidities that include obesity, hypertension, diabetes mellitus, and smoking. Children are less often and less seriously affected [38].

Pathology

Virus-mediated injury to renal tubules, podocytes, and endothelial cells has been described in autopsy studies. Viral particles have been detected in renal tubular epithelial cells and podocytes by electron microscopy and SARS-CoV-2 nuclear protein has been observed in proximal tubular cells by immunofluorescence. Acute tubular injury and collapsing glomerulopathy have been described in association with COVID-19 [39, 40]. However, the pathophysiology of the kidney injury in patients with COVID-19 has not been fully elucidated [41]. In particular, it is unclear whether kidney epithelial cells are exposed to a high viral load (as occures IN lung and nasal epithelium), since the virus is rarely detected in the blood and urine. Furthermore, the development of AKI appears to be multifactorial, similar to the pathophysiology of AKI in patients with sepsis or those who become critically ill when infected with viruses that induce hemorrhagic fevers [41].

Pathogenesis

Kidney cells appear to be vulnerable to SARS-CoV-2 infection because they express angiotensin converting enzyme 2 (ACE-2) and transmembrane serine protease 2 (TMPRSS2), two molecules required for the attachment and entry of SARS-CoV-2 into cells. These molecules are expressed mainly by renal proximal tubular cells and to a lesser extent by intercalated and principal cells of the collecting duct, distal tubular cells, parietal epithelial cells, and infiltrating immune cells. SARS-CoV-2 can cause direct damage to podocytes explaining occurrence of proteinuria and hematuria. AKI can occur secondary to the cytokines released by activated macrophages that infiltrate the kidney, activation of the angiotensin II pathway, dysregulation of complement, hypercoagulation, and microangiopathy [42]. In conclusion, the renal damage observed in patients with COVID-19 appears to be the result of multiple mechanisms [41], including direct cytopathic effects, immune-mediated damage, rhabdomyolysis, impairment of renal microcirculation, and disseminated intravascular coagulation [37]. Cases of COVID-19 associated AKI progressing chronic kidney disease (CKD) have been reported.

Presentation

Clinical manifestation of infection in children include no symptoms to mild symptoms including fever, dry cough, fatigue, and nasal congestion. Some children may have gastrointestinal symptoms including abdominal discomfort, nausea, vomiting, abdominal pain, and diarrhea. Most pediatric patients recover within 1–2 weeks. Few progress to having lower respiratory infections. Hypoxemic respiratory failure needing ventilator support and hypotension are the most common reasons for intensive care unit admission for patients with severe COVID-19. Renal manifestations, if present, are usually seen in patients with severe COVID-19 infections. Proteinuria and hematuria are common signs of renal involvement among hospitalized patients. AKI can occur in seriously ill patients and appears to result from a complex process that includes traditional risk factors such as hypotension and hypoperfusion of the kidneys and COVID-19 specific factors. Renal involvement in COVID-19 is associated with increased mortality [43]. Diagnosis is made by a real time polymerase chain reaction (RT-PCR) test to detect SARS-CoV-2 nucleic acid in nasopharyngeal swabs.

Management

Children with SARS-CoV-2 infection with mild symptoms usually only require antipyretic therapy. In cases of dehydration, vomiting, or diarrhea, the use of ibuprofen should be avoided due to the risk of AKI. As only a few cases of severe COVID-19 in children have been reported including multisystem inflammatory syndromes, limited evidence of good quality is available to recommend treatment for these patients. Some evidence suggests that intravenous corticosteroids and IVIG may be beneficial in severe cases [44]. The value of other treatments, including hydroxychloroquine, remdesivir, ivermectin, nebulized interferon alpha-2b, and oral lopinavir/ritonavir, is still unclear at the present time, and should be used only in the context of clinical trials [44]. Currently, no solid data supports that angiotensin converting enzyme inhibitors or angiotensin receptors blockers increase the susceptibility of people to a SARS-CoV-2 infection; thus, these drugs should not be discontinued in infected patients. Continuous renal replacement therapy can be used in critically ill children with AKI. Hypercoagulability leading to frequent filter clotting may occur in these children. Increased doses of unfractionated heparin, combination of heparin and regional citrate anticoagulation, or combination of prostacyclin and heparin are potential treatments for these issues. Acute peritoneal dialysis or intermittent hemodialysis can be used in patients who are hemodynamically stable [45].

Hepatitis B Virus (HBV)

Epidemiology

HBV is a partially double-stranded DNA virus comprised of an outer surface envelope (HBsAg) and an inner nucleocapsid containing the hepatitis B core antigen (HBcAg) and viral DNA. The HBcAg releases the hepatitis B antigen antigen into the circulation, and this antigen indicates the presence of infectious viral particles. Chronic HBV infection, defined as persistent circulating hepatitis B surface antigen (HBsAg), affects 5–6% of the population globally [46]. Its prevalence varies from 0.1% in the United States to 2%–7% in south Asia and 20%–30% in Pacific Islands [46]. Infants infected at birth or immunosuppressed children are most likely to be infected chronically. While only 3%–5% of viremic patients develop glomerular disease, the infection accounts for 25% of patients with specific glomerulopathies in endemic regions [47, 48]. Occult HBV infection (viral nucleic acid in liver, kidney, peripheral blood mononuclear cells or ultracentrifuged plasma, but not amplified in serum by conventional PCR) also occurs, particularly with membranous and/or IgA nephropathy [47]. Co-infection with HCV or HIV is observed in 20%–30% and 5%–10% cases, respectively, and can alter glomerular pathology and plan of management [47]. Overall, the incidence of glomerular disease attributed to HBV mirrors geographic variations in its prevalence [49, 50], and is declining in regions with universal HBV vaccination in childhood [51].

Pathology

The most common pattern of glomerular injury associated with chronic HBV viremia is MN, particularly in children [47, 48] (Fig. 4A). These patients have deposits of IgG, C3, IgM, and IgA, in subepithelial, subendothelial, and mesangial cells. HBV is also associated with polyarteritis nodosa (PAN), seen more frequently in cases of subacute or chronic viremia (weeks to years). Diffuse proliferative GN has been associated with acute viremia (days to weeks). People with chronic viremia can also develop immune-complex MPGN with or without mixed cryoglobulinemia, IgA nephropathy, focal segmental glomerulosclerosis (FSGS), mesangioproliferative GN, amyloidosis, antineutrophil cytoplasmic antigen (ANCA) negative necrotizing small-and medium-vessel vasculitis, and fibrillar or immunotactoid glomerulopathies.

Pathogenesis

Active viremia is required to cause kidney disease, either through deposition of immune complexes and/or direct viral infection [52]. The histological pattern of injury reflects the antigen in the immune complexes. Subepithelial deposits, mimicking typical MN, usually contain cationic HBeAg-IgG that readily traverses the glomerular filtration barrier as HBeAg is of relatively small size (~17 kD) [47, 48]. In contrast, anionic IgG-HBsAg complexes are larger (HBsAg is ~35–50 kD) and therefore restricted to the subendothelial space, leading to MPGN in glomeruli and PAN in medium-sized vessels [53]. HBsAg is sometimes associated with mixed cryoglobulinemia type III and direct tissue infection may cause IgA nephropathy or FSGS [47, 48].

Patients with HBV-associated MN almost always have circulating HBeAg [47, 52]. Viral genotype A and specific acquired missense mutations in the HBV X gene predispose to developing

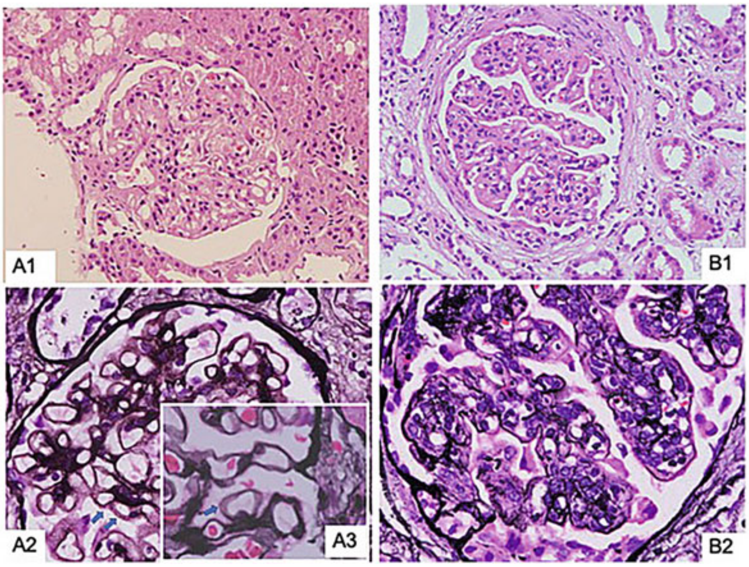

Fig. 4 Histological lesions typically associated with infection with hepatitis B (HBV) and hepatitis C (HCV) infection in children. (A) Membranous nephropathy in a 4-year-old boy with HBV DNA $>10^6$ copies per mL. H&E-stained glomerulus (A1) shows prominent glomerular basement membrane with stiff capillary walls. Silver methenamine stained glomerulus indicates "spikes" (arrows in A2) and numerous pinpoint "holes" (arrows in the inset A3) in tangential section, caused by the projections of basement membrane matrix towards the urinary space. (B) Membranoproliferative glomerulonephritis in a 12-year girl with HCV presenting with acute nephritic syndrome, nephrotic range proteinuria, and low complement C3. Hematoxylin and eosin-stained glomerulus in (B1) shows lobular accentuation, mesangial expansion, mesangial and endocapillary hypercellularity, while silver methenamine stained glomerulus in (B2) highlights the irregular capillary wall thickening with segmental glomerular basement membrane double contours. *Courtesy: Dr Geetika Singh, Department of Pathology, All India Institute of Medical Sciences, New Delhi, India.* A1 - B1 = x 200 magnifications; A2 - B2 = x400 magnifications

MN [54]. Contrary to primary MN that typically shows IgG4 deposition, lesions in HBV-associated MN contain IgG1 [55]. Presence of segmental lesions, mesangial proliferation, subendothelial or mesangial deposits, and/or tubular reticular inclusions suggest HBV-associated glomerulopathy [52, 56]. Circulating anti-phospholipase A2 receptor antibodies (anti-PLA2R), previously considered pathognomonic for primary MN, were found in a majority of patients with HBV-associated MN, and colocalized with HBV antigens within glomeruli [55].

Presentation

HBV is the major cause of MN in boys under 12 years of age. Children acquire HBV through vertical and horizontal transmission, and may not always have a history of hepatitis or active liver disease. Circulating immune complexes containing HBsAg and anti-HBs antibodies are frequently detected in the circulation, and serum levels of C3, C4, and total hemolytic complement may be decreased. While patients with MN present with nephrotic syndrome, those with MPGN have features of nephritis with or without heavy proteinuria [47]. Co-infection with HCV must be excluded in patients presenting with AKI, nephrotic syndrome and/or systemic vasculitis with hypocomplementemia and cryoglobulinemia [52]. Compared to primary PAN, HBV-associated PAN usually has worse vasculitis scores, milder skin lesions, mesenteric rather than renal involvement, and favorable response to therapy [52].

Management

As cytotoxic T cells and natural killer cells play a key role eliminating infectious hepatocytes, drugs that induce immune suppression may accelerate the progression of this disease [19]. Antiviral therapy leads to resolution of HBV-associated MN, MPGN, and/or type 3 cryoglobulinemia; monotherapy in patients that are immunosuppressed is not recommended and may be counterproductive [57]. KDIGO guidelines recommend that patients with HBV associated MN receive therapy with either interferon (IFN) or oral nucleotide (tenofovir, adefovir) or nucleoside (lamivudine, entecavir, telbivudine) reverse transcription inhibitors [57]. Conventional or pegylated IFN-α, approved for use in children ≥1-yr and ≥ 3-yr old, respectively, require subcutaneous administration for 24 weeks and 48 weeks, respectively [57]. While resistance to therapy is rare, adverse events are common and IFN-α is contraindicated in decompensated liver failure. Among oral agents, entecavir and tenofovir are preferred to lamivudine, since the latter carries high risk of resistance due to the YMDD mutation in HBV DNA polymerase [58]. Finally, the optimal duration of therapy with oral agents is uncertain, most agents are not licensed for use in children, and dose adjustments are necessary in patients with renal dysfunction [57].

Outcome

The prognosis of HBV-related MN is more favorable in children than adults, with rates of kidney failure estimated at <5% versus 25%–35%, respectively [52]. Histological lesions often resolve upon clearance of circulating HBeAg, whether spontaneously or after therapy.

Hepatitis C Virus (HCV)

Epidemiology

HCV virus is an enveloped positive sense single-stranded RNA virus of the family Flaviviridae. Infection with HCV affects 3% of the population globally, including 0.15% of children [59]. Children become infected through contaminated blood transfusions or vertical transmission and approximately 100,000 children in the United States are infected chronically with HCV [19]. Both the prevalence and genotype distribution vary markedly geographically [59]. While 75–90% of incident infections cause chronic viremia, this figure will likely decline with the use of direct-acting antivirals (DAA) [59]. Occult HCV infection is present in 30%–50% of cases with idiopathic and secondary glomerulopathies [60]. In some cases (5–10%), patients are co-infected with HIV-1, and their treatment is more challenging.

Pathology

The most common HCV-related GN is type I membranoproliferative GN (Fig. 4B), which may be accompanied by type 2 (80%) or 3 (20%) cryoglobulinemic vasculitis, typically in adulthood, after 10–15 years of acquiring HCV infection [47, 61]. MN is the second most common glomerulopathy. Chronic HCV infection might also cause tubulointerstitial injury [47] and/or acute tubular necrosis with hepatorenal syndrome [62], and increases risk of progression of CKD.

Pathogenesis

Similar to infection with HBV, glomerular injury requires active viremia. Cases of polyarteritis nodosa have been seen in people with subacute or chronic HCV viremia. Alternatively, other glomerulopathies (immune complex membranoproliferative GN, Ig A nephropathy, MN, FSGS, mesangioproliferative GN, fibrillary or immunotactoid glomerulopathies, or cryoglobulinemic TMA) are also associated with periods of chronic viremia. Usually, the glomerular lesions contain deposits, on or along the glomerular basement membrane, containing large lattice-like immune complexes, comprised of monoclonal IgM_K binding to the Fc portion of non-neutralizing, HCV-specific, IgG1 or IgG3; these IgGs ineffectively bind to certain HCV proteins (e.g., E2, NS3 or HCV RNA) [47]. Type 3 cryoglobulinemia, with circulating polyclonal IgM-polyclonal IgG immune complexes, may progress over 10–15 years to type 2 cryoglobulinemia, characterized by monoclonal production of IgM_K [48]. This overproduction of RF-IgM_K is caused by repeated B cell activation due to continued production of HCV-specific IgG to clear millions of HCV-IgG immune complexes daily, and/or molecular mimicry of host autoantigens by HCV core proteins NS5A and NS

[63]. Reactivity of IgM_K to IgG leads to rheumatoid factor activity.

Direct viral infection of glomerular and tubular cells can be demonstrated by immunochemistry, in situ hybridization and/or extraction of HCV RNA sequences [47, 48]. Disease pathogenesis may involve multiple pathways including increased expression of toll-like receptors by mesangial cells and/or generation of pro-inflammatory cytokines, insulin resistance with intrarenal production of insulin-like growth factor-1 and transforming growth factor-β, upregulated mesangial cell expression of angiotensin II type 1 receptors, and/or oxidative injury [47, 48].

Presentation

Patients with chronic HCV infection may have proteinuria, microscopic hematuria, hypertension or renal dysfunction on screening, or present with nephrotic syndrome, acute nephritis, and/or rapidly progressive GN [47, 59, 61]. Patients may have features of systemic vasculitis (purpuric rash, arthralgias) or glomerulonephritis in the presence of circulating cryoglobulins, which is termed mixed cryoglobulinemia syndrome [63]. Patients with decompensated liver disease may present with oliguric AKI.

Evaluation

KDIGO recommends that all HCV-infected patients should be screened annually for hematuria, proteinuria and reduced GFR, and undergo kidney biopsy if any of these findings persist [64]. Biopsy is also indicated in HCV-infected individuals presenting with acute nephritic syndrome, nephrotic syndrome and/or features of vasculitis. Conversely, all patients newly diagnosed with CKD should be screened for antibodies to HCV using an enzyme-linked immunoassay and qNAT for active viremia should be performed in patients with a positive immunoassay [64, 65]. Rarely, the anti-HCV immunoassay is negative while viremia is present, as may happen in early acute infection and/or in immunosuppressed hosts [64].

Management

The treatment of HCV-associated kidney disease focuses on eradicating HCV viremia, the source of nephritogenic immune complexes. Oral DAAs against HCV are now the therapy of choice since they enable sustained virological response in over 90% cases, across all genotypes, within 4–8 weeks [66, 67], and eliminate cryoglobulinemia [68]. Hence, the guidelines from KDIGO [64]; the European Association for the Study of the Liver (EASL 2018) [69]; the American Association for the Study of Liver Diseases/Infectious Diseases Society of America (AASLD/IDA) [70]; and the Sweden guidelines [71], all recommend therapy with DAAs for all HCV-associated glomerular diseases, particularly MPGN. Therapy with interferon-alpha (IFN-α) is no longer recommended as it is associated with low rate of virological response (<65%), non-sustained remission, need for prolonged therapy (48-weeks), poor patient tolerance and, in allograft recipients, risk of humoral rejection [66, 67].

Patients with HCV-associated glomerular disease with stable kidney function and non-nephrotic range proteinuria are initially treated with DAAs, usually in a combination of agents targeting different nonstructural proteins (NS5A, NS5B, and NS3/4A), for a duration of 12-weeks [66, 67]. Dose modification for decreased GFR is often required. Evidence on the safety and efficacy of DAAs in children is limited to combinations of sofosbuvir with ledipasvir, sofosbuvir with ribavirin and glecaprevir with pibrentasvir, all of which are approved for therapy in patients older than 12 years. Patients presenting with rapidly progressive kidney failure, acute cryoglobulinemia or nephrotic syndrome are candidates for additional measures to clear circulating immune complexes or alleviate inflammatory symptoms, such as immunosuppression and therapeutic apheresis [47, 48, 64]. Therapy with rituximab is more effective than conventional immunosuppression in prospective controlled studies in adults with cryoglobulinemic vasculitis or diffuse membranoproliferative GN, but carries risk of reactivation of HCV infection [64, 72].

Outcomes

Meta-analyses suggest that IFN-α therapy leads to reduced proteinuria and improved eGFR, although as mentioned, this therapy is no longer suggested [73]. Recent studies indicate sustained virological response in 95% of patients treated with DAAs, along with remission of kidney disease, reduced rate of decline of GFR and/or regression of glomerular lesions, particularly if therapy is initiated early [74].

Viral Hemorrhagic Fevers

Dengue Virus

Dengue virus is a positive sense single-stranded RNA virus of the *Flaviviridae* family that causes dengue fever, dengue hemorrhagic fever (DHF) and/or dengue shock syndrome (DSS). Infection is caused by one of four serotypes, is transmitted by the female *Aedes aegypti* mosquito, and is endemic in Southeast Asia, Latin America, and the Pacific Islands. Classic dengue usually resolves spontaneously and is not lethal; however, patients with severe infection are at risk of multiorgan dysfunction and AKI [75, 76]. AKI is observed in 0.9–10% of admitted children and 2–36% adults and is chiefly caused by ischemic hypoperfusion, acute inflammatory response with capillary leak, rhabdomyolysis and/or nephrotoxic drugs used to treat disease [75, 77]. Abnormalities in serum electrolytes (hyponatremia, hypokalemia) and the urine (proteinuria, microscopic hematuria) are observed in 20–80% patients, particularly in those with severe disease [75, 78]. Hyponatremia, which is tenfold more frequent than in non-dengue febrile illnesses, is typically from the syndrome of inappropriate anti-diuretic hormone release, intravenous overhydration and/or use of hypotonic fluids [78]. Glomerulonephritis with mesangial hypercellularity or diffuse proliferation may occur from direct viral cytopathic effects and/or immune or IgM deposition [77]. Rarely, thrombotic microangiopathy is reported [79].

Diagnosis of dengue infection is based on detection of NS1 antigen (<5 days) or IgM antibody (beyond day 4) by ELISA in the appropriate clinical context [75]. Laboratory abnormalities include increased hematocrit, severe thrombocytopenia, leukopenia, relative lymphocytosis, and/or abnormal coagulation parameters. No specific antiviral treatments are available and as such management focuses on fluid resuscitation and replacement titrated to maintain hemodynamic parameters and normalization of hematocrit, as per WHO guidelines [76]. The presence of AKI increases the risk of mortality in patients with DSS/DHF from 12–44% to >60% [75, 80]. Fluid overload is common in severe DSS and is the most common indication for kidney replacement therapy [75, 78]. Immunosuppression should be avoided in patients with glomerulonephritis; most patients recover with supportive care [75, 77].

Yellow Fever

Yellow fever virus is caused by a positive sense single-stranded enveloped RNA virus of the *Flaviviridae* family which is transmitted by the mosquito *Aedes aegypti* [81]. The infection, which endemic in certain tropical countries in Africa and South America, presents as an acute febrile illness that may progress rapidly to have hemorrhagic features and multiorgan dysfunction [82]. Patients with hemorrhagic manifestations, liver injury, disseminated intravascular coagulation, and shock are at risk of severe disease and oliguric AKI, which is manifested as acute tubular necrosis [82]. Diagnosis relies on isolating the virus by PCR and/or demonstrating serum IgM; liver biopsy, if performed, shows characteristic Councilman bodies. Management is chiefly supportive [81].

Ebola Virus

Like other Filovirus, Ebola is an enveloped, non-segmented, negative-sense RNA virus. This virus has been associated with outbreaks of fatal hemorrhagic disease in Africa since the 1970s, and an epidemic in 2013–16 leading to 11,000 fatalities in western Africa [83]. Disease course comprises of a prodromal phase, followed by a febrile period, then gastrointestinal symptoms, and finally, severe hypovolemic and septic shock, respiratory failure, and multiorgan dysfunction, with only minor bleeding manifestations [83, 84]. Patients with multiorgan dysfunction are at high risk of AKI and mortality [85]. Case fatality rates of 40–90% are reported at extremes of age and in resource-constrained settings [83, 84]. With no specific antiviral therapy, supportive care focuses on timely provision of cardiorespiratory support, treating/preventing hypovolemia, correction of electrolyte and metabolic abnormalities, and if indicated, kidney replacement therapy [83, 84]. The FDA recently approved a vaccine for Ebola, which is given as a single dose, and appears to be safe and protective against Zaire ebolavirus which has caused deadly Ebola outbreaks.

Hantavirus

Hantavirus is a negative sense enveloped RNA viruses belonging to the *Bunyaviridae* family and *Orthohantavirus* genus. These viruses are transmitted to humans by exposure to aerosolized rodent urine, feces, or saliva [86]. Human disease, reported with about 30 different hantaviruses across the world, has five phases, including febrile, hypotensive, oliguric, polyuric, and convalescent phases, with severity varying by virus type [86]. Transient nonselective proteinuria and microscopic hematuria are common findings in infection with all hantaviruses [86]. AKI is reported chiefly with hantavirus cardiopulmonary syndrome in United States and South America (Sin Nombre and Andes viruses) and with hemorrhagic fever and renal syndrome (Hantaan, Dobrava-Belgrade, Seoul, and Puumula viruses) in Asia and Europe [87]. AKI associated with Hantavirus is usually mild, except in infection with Hantaan or Dobrava viruses [86, 87]. When AKI occurs, GFR typically falls abruptly due to altered hemodynamics mediated by increased vascular permeability, akin to septic shock. Other contributors to renal injury include endothelial injury, complement activation, cytokine-mediated tubular, and interstitial damage [88]. Kidney biopsy typically shows either acute interstitial nephritis or acute tubular necrosis, with or without interstitial edema and hemorrhage [89].

Diagnosis is usually made by demonstrating IgM antibodies (within ≤ 3 weeks), a four-fold rise in IgG titers, or amplification of viral RNA in blood cells or serum by nested reverse-transcriptase PCR [90]. Management focuses on ensuring cardiorespiratory support; therapy with ribavirin may ameliorate disease if initiated early [91] but is ineffective when delayed to cardiopulmonary phase [92]. Kidney replacement therapy is occasionally required for patients with severe fluid overload or electrolyte abnormalities.

Congo-Crimean Hemorrhagic Fever (CCHF)

CCHF is caused by infection with a tick-born single-stranded RNA virus (*Nairovirus*) of the B*unyaviridae* family. This virus causes a frequently lethal viral hemorrhagic fever in Western Asia, the Balkans, Southern Europe, and most of Africa. Patients may become lethargic and develop hepatic and kidney failure. Ribavirin and immunoglobulins have been used in several cases but controlled studies are required to prove their efficacy in reducing mortality [19] .

Rift Valley Fever Virus (RVFV)

RVFV is a negative-sense single-stranded RNA virus from the family *Bunyaviridae* transmitted via mosquito vectors [93]. It is a zoonotic pathogen that primarily affects ruminants but can be lethal in humans. Although the initial cases were restricted to sub-Saharan Africa, most recent outbreaks were detected in the Middle East, raising concerns that the virus could spread to Europe and Asia. The infection can present as a mild self-limiting illness in many cases, or as a vasculitis with renal involvement or fatal hemorrhagic illness less frequently [19]. There are no specific treatments for RVFV.

Lassa hemorrhagic fever is produced by the Lassa virus, a segmented negative sense single-stranded RNA arenavirus, which is endemic in West African countries [94].The annual incidence of infection in West Africa is between 300,00 and 500,000 cases. Many of those infected by the virus do not develop symptoms, but approximately 10% can develop a fulminant hemorrhagic fever, with proteinuria, hematuria, and acute kidney injury, resulting in ~5000 deaths per year. Ribavirin given early in the course of the illness along with intensive fluid replacement and hemodynamic support appear to reduce the mortality of this disease [19].

Marburg Virus

The Marburg virus is a non-segmented negative sense RNA virus belonging to the order of Mononegavirales. The reservoir host of Marburg virus is the African fruit bat *Rousettus aegyptiacus.* The Marburg virus causes hemorrhagic fevers in humans and nonhuman primates [19]. The initial outbreaks were recognized in Marburg and Frankfurt Germany, Belgrade, and Serbia. This disease is associated with hypotension, extracellular fluid volume contraction, and coagulation disorders, leading to fulminant shock if not treated with aggressive hemodynamic support. There is currently no specific treatment or vaccine.

Argentine Hemorrhagic Fever (AHF)

AHF is a rodent-borne illness caused by the Junin virus that is endemic in the humid pampas of Argentina [95]. The Junin virus is an arenavirus that contains a bisegmented negative sense RNA genome, and spreads through aerosolization of host rodent excreta. Most infections result in clinical disease (80%), with a fatality rate of 15% to 30% if left untreated. During the first phase of the illness patients show leukopenia and thrombocytopenia, proteinuria, and hematuria. Liver enzymes are elevated, but BUN and serum creatinine are normal in the absence of dehydration or shock [95]. Specific therapy against AHF includes infusion of immune plasma during the prodromal phase of illness. However, there are no effective therapies for severely ill patients in the neurological-hemorrhagic phase. Ribavirin has been used in place of immune plasma in the early stages. A live attenuated vaccine is available that has reduced the incidence of AHF. Machupo virus, closely related to Junin virus, is found in Bolivia and can also causes prominent neurological symptoms and systemic hemorrhagic features, leading to shock and acute kidney injury in the worse cases [19].

HIV-Associated Nephropathies

Epidemiology: Approximately 2.8 million children under 19 years of age were living with HIV in 2019 [96]. Every day in 2019 approximately 880 children became infected with HIV-1 and 310 children died from AIDS-related causes, mainly because they did not have access to appropriate care [96]. Before the modern antiretroviral therapy (ART) era, persistent proteinuria and severe forms of microvascular thrombotic microangiopathies (TMAs) were frequently seen in adults and children with advanced HIV disease [97–99]. The incidence of these diseases fell dramatically to <10% and <0.5%, respectively, in subsequent years with the use of modern ART [99–101]. However, children need to receive continuous ART throughout their childhood to remain in good health, which creates significant public health challenges all over the world. Unfortunately, almost half of the children living with HIV worldwide are not receiving appropriate ART and as such, more than 100,000 children have died of an AIDS related illness since 2018 [96]. In addition, we continue to see children developing HIV-associated nephropathy (HIVAN) in the United States [101].

Over 80% of all children living with HIV reside in Africa. People from African ancestry have an increased risk of developing HIV-associated nephropathy (HIVAN) and other HIV-chronic kidney diseases (HIV-CKDs) [101, 102]. This increased risk has been attributed to Apoliprotein-1 (APOL1) genetic variants G1 and G2 [103]; these variants increase the lifetime risk of young adults who are not receiving appropriate ART to develop HIVAN by ~50% [104]. However, the relative prevalence of these APOL1 risk alleles is low, so most children living with HIV develop HIVAN independently of these risk variants [105–108]. Therefore, other unknown yet genetic factors associated with the African ancestry likely have additional roles precipitating HIVAN.

Pathology

HIV-associated kidney diseases have been recently classified into three main pathological categories [109]: (1) Glomerular-dominant disorders, including podocytopathies and immune complex-mediated glomerular diseases; (2) Vascular-dominant disorders, including TMA and an atypical form of HUS; and (3) Tubulointerstitial-dominant disorders due to ischemia/hypovolemia, nephrotoxic drugs, including ART (i.e., tenofovir, indinavir, aminoglycosides, amphotericin B, foscarnet, cidofovir, trimethoprim-sulfamethoxazole, and acyclovir), renal infections with bacteria, fungi, protozoans, and many of the viruses discussed above (HCV, BK, adenovirus, and/or herpes viruses).

Four subtypes of podocytopathies have been described [109]: (1) Classic HIVAN (defined as CG and tubular microcyst formation with interstitial inflammation and tubular injury); (2) Focal segmental glomerulosclerosis (FSGS) not otherwise specified (NOS) (defined as the presence of non-collapsing FSGS, with less prominent tubulointerstitial disease); (3) Diffuse mesangial hypercellularity; and (4) Minimal change disease (rare). All of these renal diseases show podocyte foot process effacement and proteinuria, without significant immune complex deposition. Pathologists recommend distinguishing classic HIVAN from FSGS (NOS), since HIV-causality can be proven in classic HIVAN [109]. However, ART can mask the typical presentation of classic HIVAN, and young children are less likely to develop CG and instead frequently develop mesangial hyperplasia and/or FSGS in combination with microcystic tubular lesions leading to renal enlargement (Fig. 5). Therefore, the diagnosis of childhood HIVAN should take into consideration the age of the child, as well as the typical clinical and renal histological features characteristic of this renal disease.

Several types of HIV-associated immune-complex kidney diseases (HIVICD) have been reported in adults and children living with HIV [110]. These diseases include MPGN, post-infectious GN, GN associated with mixed cryoglobulinemia, IgA nephropathy, lupus-like GN (with negative lupus serology and lack of lupus symptoms), MN, and renal diseases with a mixed histological pattern consistent with both HIVAN and HIVICD [109]. A large number of cases of HIVICD have been reported in South African children with proteinuria (~50%) [110]. Thus, given the heterogenous spectrum of all HIVICD renal diseases and the difficulties in establishing HIV causality, pathologists have recommended to replace the term “HIV immune complex kidney disease” with the specific description of the type of immune complex disease in the setting of HIV [109].

Several cases of TMA were reported in people living with HIV during the early years of the AIDS epidemic [98, 111]. In many cases, the TMA lesions were asymptomatic and were detected during autopsies [112]. Endothelial injury appears to be the

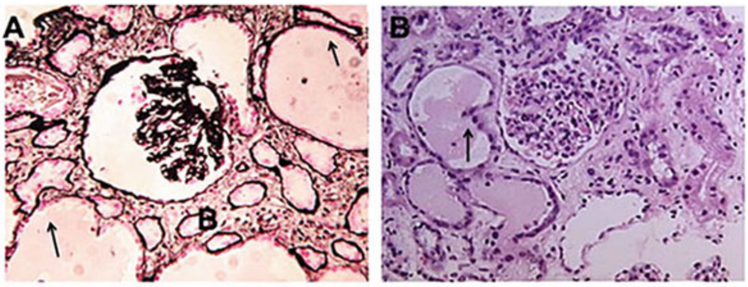

Fig. 5 Panels A and B show representative kidney sections from children with HIVAN. Panel A shows a kidney biopsy with collapsing glomerulopathy stained with periodic acid Schiff. Panel B shows a kidney biopsy with mesangial expansion and enlarged glomeruli stained with hematoxylin and eosin. Both panels show the tubular microcystic changes characteristics of childhood HIVAN (arrows) (both x200 magnifications)

primary event in the pathogenesis of TMA, causing the activation and deposition of platelets in arterioles and capillaries. In contrast, the atypical cases of HIV-HUS reported in young children during the pre-ART era [113], revealed TMA lesions characterized by the accumulation of fibrin in combination with glomerular and tubulointerstitial proliferative changes [113]. A deficiency in the von-Willebrand factor cleaving protease ADAMTS13 was found in one adolescent HIV+ female with thrombotic thrombocytopenic purpura (TTP) who developed a hemorrhagic stroke [114]. These TMA lesions were characterized by the intravascular accumulation of large vWF-fragments and platelets rather than fibrin.

Pathogenesis

HIV-1 is an enveloped double-stranded RNA virus. Retroviruses such as these carry the enzyme reverse transcriptase, which allows the virus to copy RNA into DNA to infect human cells. Most of our knowledge related to the pathogenesis of HIVAN is based on studies done in HIV-transgenic (Tg) mice or rats [102]. These models provided definitive evidence that the expression of HIV-transcripts in renal epithelial cells play a crucial role in the pathogenesis of HIVAN. However, both the infection and viral replication processes are bypassed in transgenic mice/rats and a key event that was not apparent from these rodent studies was how renal epithelial cells become infected in vivo. Renal epithelial cells do not express the CD4 molecule, which is the major HIV-1 receptor, and must use an alternative mechanism to become infected. One study done in 1998 showed that primary HIV isolates derived from children with HIVAN were able to induce a CD4 independent low level productive infection of renal tubular epithelial cells cultured from the urine of children with HIV-CKDs [98]. This study demonstrated that infected renal epithelial cells were able to transfer viruses to co-cultured HIV-negative mononuclear cells even after 20 days in culture [98]. In addition, this study showed that the most effective way to infect cultured renal epithelial cells is through a “Trojan horse” like mechanism. In this process, HIV+ mononuclear cells established close contact with renal epithelial cells, and released viruses into a “virological synapse” space formed between the cells. Subsequently, HIV is taken up by the epithelial cells via endocytosis (Fig. 6), and through mechanisms that are not clearly understood, induces a low-level and transient productive infection in these cells [98]**.** Viral transcripts in podocytes and tubular epithelial cells have been detected in adults with HIVAN [115], and these studies hypothesize that the kidney might become an HIV-reservoir independent from the blood compartment [116]. Other studies demonstrated that transmembrane-TNF-α (tm-TNF- α) plays a key role facilitating the infection of CD4 negative podocytes and tubular epithelial cells by increasing the uptake of viral particles via clathrin-mediated endocytosis, and by increasing the production of viral transcripts via the activation of NF-kB [117]. Heparan sulfate proteoglycans (HSPG) also facilitate the infection of renal epithelial cells by increasing the attachment and endocytosis of HIV-1 [117]. Interestingly, tm-TNF-α can act both as a ligand, releasing soluble TNF-α that activates the TNF receptors, and as a receptor, facilitating the formation of virological synapses between mononuclear and kidney epithelial cells [102]. These findings, together with the high TNF-α plasma levels found in young HIV-Tg_{26} mice and children with HIVAN, support the notion that TNF-α plays an important role in the pathogenesis of childhood HIVAN [102].

Another unique feature of HIVAN is the finding of de-differentiation and proliferation of podocytes and tubular epithelial cells leading to the collapse of glomerular capillaries and formation of tubular microcysts and renal enlargement. Previous studies done in cultured murine epithelial cells immortalized with the SV-40 large T antigen showed that HIV-Nef increased the proliferation of these cells [118], supporting that HIV-1 can induce direct proliferative changes in renal epithelial cells. However, these findings were not reproduced in cultured primary human renal epithelial cells. Furthermore, cultured human renal epithelial cells infected with HIV-1 showed poor viability and proliferative capacity [98]**.** In contrast, cytokines and heparin binding growth factors induce significant proliferation of primary renal epithelial cells cultured from

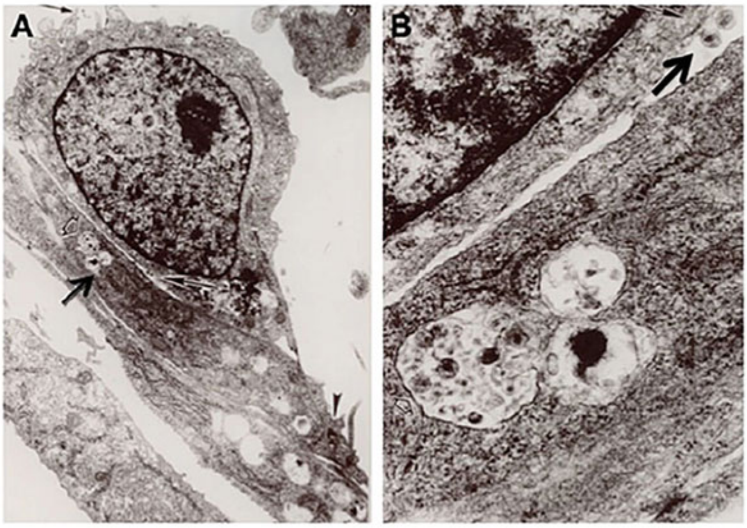

Fig. 6 Electron micrographs showing a mononuclear cell on top of renal tubular epithelial cells (RTECs) cultured from a child with HIVAN. The arrowhead in panel A points to a tight junction between RTECs. The arrow points to HIV viral particles inside the RTEC. Panel B shows a higher magnification of the viral particles inside the RTEC, as well as viral particles in the space between the mononuclear cell and RTEC (arrow). Original magnification x10,000 (A) and x50,000 (B)

HIV-Tg$_{26}$ mice and children with HIV-CKDs [102, 119]. In fact, both HIV-Tg$_{26}$ mice and children with HIVAN had up-regulated expression of renal heparan sulfate proteoglycans (HSPG) that facilitate the recruitment of the HIV-Tat protein [102] and other heparin binding growth factors. Considering that podocytes are terminally differentiated cells, it has been postulated that they may detach or die when forced to enter the mitotic cell cycle under the influence of growth factors [120]. Injured podocytes appear to be replaced by less differentiated parietal epithelial or progenitor cells, that appear to be highly sensitive to the mitogenic effects of heparin binding growth factors [102]. In support of this notion HIV-Tat, acting in synergy with FGF-2 and other heparin binding growth factors, can disrupt the cytoskeletal structure of podocytes and glomerular endothelial cells, and precipitate HIVAN in young HIV-Tg$_{26}$ mice [121–123]. Finally, other cytokines that are released by HIV-infected cells, including TNF-α and IFN-γ, can induce the expression of APOL1 in renal epithelial cells [124]. Since up-regulated expression of the APOL1 risk variants G1/G2 reduces the viability of renal epithelial cells [124, 125], many speculate that HIV may act as a second hit to precipitate HIVAN by increasing the cytotoxicity of APOL1 in podocytes, rather than by inducing direct proliferative changes in these cells.

The pathogenesis of HIVICD kidney diseases in the setting of HIV is not well understood, and varies depending on each of the clinical forms described above. In general, HIV infection is associated with activation and dysregulation of the immune system that facilitates the formation of immune complexes and their deposition in the kidney. Co-infections with other agents may exacerbate HIVICD. Renal deposits of IgM, IgG, IgA, and complement (including C3, C4 and C1q) are typically found in these cases [126]. Interestingly, renal biopsies done in South Africa showed “a ball in cup” appearance of subepithelial immune deposits in the glomerular basement membrane by electron microscopy, although these lesions have not been reported in other studies [110]. Tubulo-reticular inclusion bodies are detected in HIVICD as well as HIVAN, hepatitis C and lupus-like nephritis [126]. One case report involving two white men suggested that HIV-1 can have a direct role in the pathogenesis of IgA nephropathy [127]. Circulating anti-HIV IgG and IgA antibodies were detected in the circulation of both patients, and isolated from the renal biopsy of one of them [127]. HIV p24 and gp120 antigens were also isolated from the renal tissue of both patients [127]. However, it remains unclear whether IgA nephropathy in the setting of HIV is due to the deposition of IgA directed against viral antigens or from other causes. Finally, other secondary causes of HIVICD should be ruled out in all cases of MN (i.e., HBV co-infection, or anti-PLA2R autoantibodies) and membranoproliferative glomerulonephritis (i.e., HCV co-infection).

The pathogenesis of HIV-associated vascular diseases is multifactorial and characterized by the development of TMA lesions. Endothelial injury is the primary event leading to development of TMA and HUS in children living with a high HIV viral load. Chronic endothelial injury, activation, and increased leukocyte adherence have been detected in the aortic endothelium of HIV-infected patients [128]. Endotoxin, viral co-infections (e.g., CMV), immune complexes, and drugs are among many factors that can induce endothelial injury and activation in HIV+ people. A direct role for HIV-1 inducing endothelial injury and dysregulation is supported by the presence of the HIV-1 p24 antigen in endothelial cells [111]. HIV-productive infection of the vascular endothelium remains a controversial issue, since endothelial cells do not express CD4. Previous studies showed that HIV-1 can FUSE to cultured renal glomerular endothelial cells through a CD4 independent CXCR-4 mediated mechanism [129], but HIV transcripts have not been detected in glomerular endothelial cells. Alternatively, endothelial cells can be activated by HIV-cytokines and viral proteins, such as Tat and gp120 [122, 130]. In fact, the dramatic reduction in the incidence of TMA lesions, and markers of endothelial injury/activation during the modern-ART era [131], strongly suggest that HIV-1 plays a direct role in the pathogenesis of these lesions.

Presentation and Outcomes

Childhood HIVAN is a late manifestation of HIV-infection. Children with HIVAN usually have a clinical history of sustained high viral load and low CD4 counts for months. Isolated persistent proteinuria is the first clinical sign of HIVAN. Edema, hypertension, or azotemia, are rare in the early stages of HIVAN. All types of renal epithelial cells, urothelial cells, inflammatory cells, and/or casts can be detected in the urine, including urinary epithelial cells grouped together forming microcysts in fresh urine specimens before centrifugation [132]. Renal sonograms may show enlarged echogenic kidneys. Microscopic hematuria can be present, but is more frequently seen in children with HIVICD. In fact, children with macroscopic hematuria or microscopic hematuria without proteinuria, increased BUN or serum creatinine without proteinuria, and hematuria or proteinuria in White, Asian or Hispanic children, require a more extensive evaluation for the presence of other kidney diseases. A definitive diagnosis of HIVAN can only be made on a renal biopsy. Studies done in South Africa [110], showed that almost 50% of children with suspected HIVAN and persistent proteinuria actually had renal histological features consistent with other renal diseases. Limited long-term data are available to predict the outcome of HIV-CKDs during the modern ART era. A recent study showed that HIVAN had a worse prognosis than HIVICD [101]. It appears that once the clinical and renal histological features of HIVAN are well established, current treatments might not prevent progression to kidney failure [101]. However, even HIVICD cases have been progressing at a slower rate for several years [101]. In addition, many HIV+ children and adolescents of African descent treated with ART for years can still have mild but persistent reductions in GFR (< 80 ml/min/1.73 m^2), and are at high risk of developing chronic kidney failure in adulthood [101].

Atypical cases of HIV-HUS were reported in children in the pre-ART era. The presentation of HIV-HUS was insidious and followed a progressive clinical course to kidney failure or death due to infections and bleeding complications [113]. In another case, an adolescent female with HIV-TTP developed a stroke in the hospital, but was treated rapidly with ART and plasma exchange; she continued to improve with sustained virologic suppression and eventually had recovery of the platelet count and no major neurological or kidney sequela [114]. Thus, it appears that the early recognition and treatment of these cases can improve their outcome.

Management: Modern ART has substantially improved the clinical outcome of all children living with HIV kidney diseases [100, 101]. Nephrologists should work in close collaboration with HIV-experts in the treatment of these patients. Updated guidelines for the management of HIV-chronic kidney diseases [133], and the panel on antiretroviral (ARV) therapy and medical management of children living with HIV provide useful information for this purpose. ARV-naïve children and adolescents should begin their treatment with two nucleoside/nucleotide reverse transcriptase inhibitors (NRTIs), plus one additional drug that could be a non-nucleoside reverse transcriptase inhibitor (NNRTIs), an integrase strand transfer inhibitor (INSTI), or a pharmacokinetic (PK)-enhanced protease inhibitor (PI). All NRTI, except for abacavir, are excreted by the kidney and their dosage should be adjusted based on kidney function. Integrase inhibitors and CCR5 antagonists can be used at similar dosages in children with impaired kidney function. Tenofovir disoproxil fumarate (TDF) is an effective ARV drug that shares the mechanism of action of NRTIs and is used widely to prevent and treat HIV/AIDS in combination with emtricitabine. However, it can induce renal tubular injury, isolated hypophosphatemia or glycosuria, Fanconi Syndrome, and/or bone disorders. For these reasons, it is not approved by the FDA in children under 2 years of age. Most recently, the FDA has approved the use of tenofovir alafenamide (TAF), which causes less renal toxicity and can be used in patients with GFR >30 ml/min/1.73 m^2. TAF appears to be as effective as TDF in achieving or maintaining virological suppression. In particular, children receiving NRTIS in combination with other nephrotoxic drugs (listed above when discussing the tubulointerstitial-dominant disorders in the setting of HIV), should be monitored more closely. Any change in serum creatinine levels, proteinuria, crystalluria, extracellular fluid volume, or acid-base status should alert physicians to the potential toxicity of these drugs. Overall, it remains to be determined how modern ART affects the renal outcome of children HIVICD, but maintaining a suppressed viral load appears to improve the outcome of these patients [101]. Angiotensin converting enzyme inhibitors (ACEi) are recommended for the treatment of proteinuria and hypertension in all children with HIV-CKDs [133]. Young children taking ACEi should be monitored more closely as they are at higher risk of becoming dehydrated secondary to diarrhea or vomiting, and developing AKI. In addition, they may develop salt wasting tubular disorders that put them a higher risk of becoming dehydrated when infected with other viruses. As ACEi can cause fetal malformations, they should be used with great caution in adolescent females with the potential for pregnancy. Steroids are not effective in children with HIVAN, but may provide benefits in children with undetectable viral loads and HIVICD [101]. Data regarding the optimal treatment with HIVICD are limited. The use of immunosuppressive drugs in children and adolescents living with HIV may exacerbate other infections, including tuberculosis in developing countries, and as such these risks should be weighed against potential benefits. Unfortunately, no randomized case-controlled studies have been performed in children with HIVICD and as such no definitive recommendations can be given regarding the use of steroids in these patients.

HIV+ children with end stage kidney failure should be treated with dialysis or kidney transplantation. The outcome of dialysis during the modern ART era has improved, but there are no studies comparing the outcome of HIV+ vs. HIV-children on dialysis. The presence of cardiovascular disease is associated with a higher mortality in HIV+ children undergoing dialysis [134]. Peritoneal dialysis is used more often in resource-limited countries, while hemodialysis is the preferred modality in the USA. The peritoneal fluid contains infections HIV-1 and should be handled with caution. Overall, the main priority should be to suppress the viral load in order to prevent infections and cardiovascular complications, and make these patients eligible for a kidney transplant. Successful kidney transplantation has happened in selected adult patients with undetectable viral loads, both in the United States and Europe. They have shown equivalent patient and allograft survival rates when compared to HIV- recipients [135, 136]. In the USA, no evidence of recurrent de novo FSGS, HIVAN, or nephrotic range proteinuria has been reported in HIV+ kidney recipients [135]. However, these patients do have higher rates of acute rejection, delayed graft function, and drug interactions. Finally, due to the limited availability of kidney donors, surgeons in South Africa and the USA are performing kidney transplants between HIV+ donors and HIV+ recipients with promising preliminary results [135, 137].

Abstract

Sickle cell disease (SCD) is one of the most common genetic disorders in the United States, affecting over 100,000 Americans and millions of people worldwide, primarily of African or Mediterranean descent. SCD is a group of hemoglobinopathies inherited in an autosomal recessive fashion. Nearly all organ systems are affected by SCD, including the kidneys. The renal manifestations of SCD are known as sickle cell nephropathy (SCN). Multiple pathogenic processes contribute to development of SCN, notably renal ischemia and hemolysis, which result in both glomerular and tubulointerstitial

disease. Clinically significant complications of SCD include hyperfiltration, albuminuria, hyposthenuria, hematuria, hypertension, acute kidney injury (AKI), and chronic kidney disease (CKD). Despite these complications, occurrence of end-stage kidney disease (ESKD) is relatively uncommon, particularly in children. Of those who progress to ESKD, both dialysis and transplantation are viable treatments. While transplantation in SCN is associated with increased complications compared to other causes of ESKD, it is preferred over dialysis due to more favorable outcomes.

Introduction

Sickle cell disease (SCD) is one of the most common genetic disorders in the United States, affecting over 100,000 Americans as well as millions of people worldwide, primarily of African or Mediterranean descent [1]. SCD is inherited in an autosomal recessive fashion. Sickle hemoglobin (HgbS) and other hemoglobin variants arose out of genetic selection due to the fact that heterozygosity for HgbS confers some resistance to malarial infection with a resultant survival advantage in endemic areas. All forms of SCD are the result of mutations in the two genes that encode β-globin, a major component of adult hemoglobin. The most common form of SCD is homozygous SS disease, also called sickle cell anemia (SCA). Other variants of SCD are the result of compound heterozygosity for HgbS and other β-globin variants, including SC, Sβ^+thalassemia, and Sβ^0thalassemia. All individuals who are homozygous or compound heterozygous for HgbS exhibit clinical manifestations of SCD. However, there is significant variability in clinical severity, primarily related to genotype. Patients with SS disease generally have the most severe phenotype followed by individuals with Sβ^0 thalassemia, whereas those with SC and Sβ^+ thalassemia tend to have milder clinical phenotypes.

HgbS polymerizes in the deoxygenated state and leads to red blood cell sickling, which, in turn, leads to the two major pathogenic processes of SCD, *vaso-occlusion* and *hemolysis*. Vaso-occlusion is associated with tissue ischemia, and hemolysis results not only in anemia but also in endothelial activation, inflammation, and vasculopathy. Nearly all organ systems are affected by SCD, leading to the well-recognized complications of pain crises, acute chest syndrome, infection (due to auto-infarction of the spleen early in life), and cerebrovascular accidents. The kidneys are susceptible to injury by multiple mechanisms that contribute further to the significant morbidity and mortality associated with SCD. The renal manifestations of SCD, which have been collectively termed “sickle cell nephropathy” (SCN), are summarized in Fig. 1. This chapter will address the current understanding of the pathogenesis, clinical presentation, management, and prognosis of SCN.

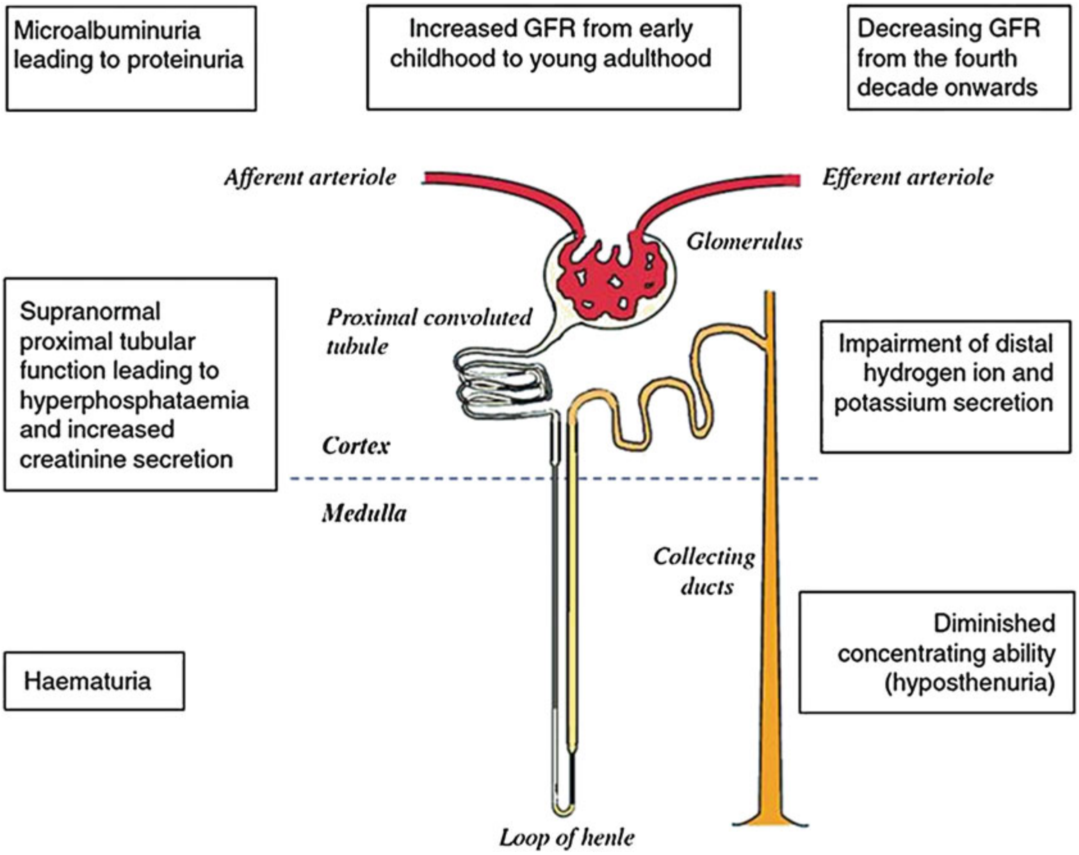
Pathogenesis and Pathology of Sickle Cell Nephropathy

The two major underlying pathophysiologic processes in SCD, vaso-occlusion and hemolysis, can result in both glomerular and tubulointerstitial involvement and damage, as illustrated in Fig. 2. In addition, medications utilized for the treatment of SCD, notably nonsteroidal anti-inflammatory drugs (NSAIDs) and chelating agents, can also cause kidney damage. In the last few decades, the mechanisms by which renal complications of SCD arise has been greatly facilitated by the availability of transgenic mice expressing sickle hemoglobin as well as intervention trials in both children and adults.

Glomerular Disease

Glomerular Disease Pathogenesis

The earliest manifestation of SCN is glomerular hyperfiltration, which is clinically evident as an

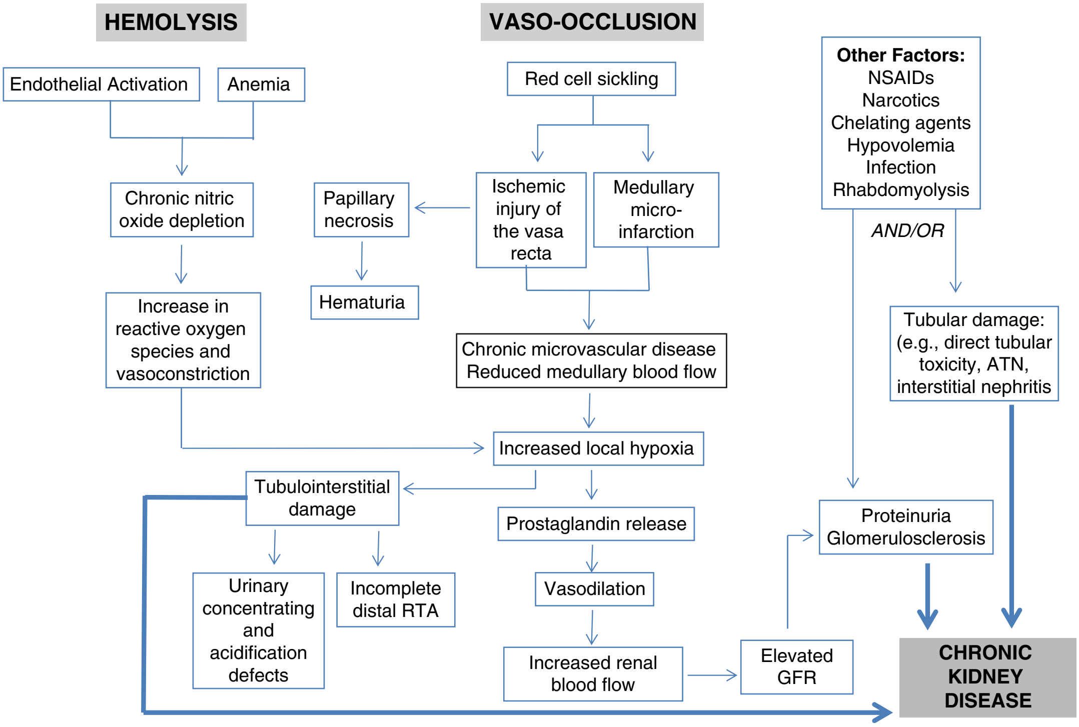


Microalbuminuria leading to proteinuria
Increased GFR from early childhood to young adulthood
Decreasing GFR from the fourth decade onwards
Afferent arteriole
Efferent arteriole
Glomerulus
Supranormal proximal tubular function leading to hyperphosphataemia and increased creatinine secretion
Proximal convoluted tubule
Impairment of distal hydrogen ion and potassium secretion
Cortex
Medulla
Collecting ducts
Diminished concentrating ability (hyposthenuria)
Haematuria
Loop of henle

Fig. 1 Renal abnormalities in sickle cell disease. A representation of the renal nephron demonstrating the regions damaged in sickle cell disease leading to the clinical manifestations of sickle cell nephropathy. *GFR* glomerular filtration rate. (Reprinted from Sharpe and Thein [51], with permission)

elevated glomerular filtration rate (GFR) starting in infancy in the vast majority of affected patients [2]. Multiple mechanisms for hyperfiltration have been proposed [3]. Animal models and patients with SCD demonstrate potentially reversible increase in renal blood flow and a decrease in renal vascular resistance. Localized prostaglandin (PG) release and increased nitric oxide synthase in response to hypoxia can also result in increased renal blood flow. The role of increased PG release as a key mechanism for the increased renal blood flow (RBF) and glomerular hyperfiltration seen in SCD is supported by the finding that indomethacin (a PG inhibitor) causes significant reductions in GFR and RBF in SCD patients but minimal or no decrease in healthy controls.

Hemolysis can also contribute to elevated GFR, via induction of heme oxygenase-1 (HO-1) in renal tubules, interstitial cells, and the vasculature as well as circulating endothelial cells [4]. HO-1 is the rate-limiting enzyme in the degradation of heme, converting heme to biliverdin, with resultant iron release and carbon monoxide (CO) production. Both biliverdin and CO are potent antioxidants, and CO acts locally as a vasorelaxant, thus increasing both the total RBF and GFR. Endothelin-1 (ET-1) has also been implicated in the progression of SCN due to its vasoconstrictive and pro-inflammatory effects. ET-1 is released in response to hypoxia, angiotensin II, and inflammatory cytokinesis, and it is increased in patients with SCD [5]. ET-1 leads to production of reactive oxygen species through the endothelin type A (ETA) receptor, the expression of which is upregulated in SCD mouse models. Animal studies suggest that treatment with an



HEMOLYSIS
VASO-OCCLUSION
Endothelial Activation
Anemia
Chronic nitric oxide depletion
Increase in reactive oxygen species and vasoconstriction
Red cell sickling
Papillary necrosis
Hematuria
Ischemic injury of the vasa recta
Medullary micro-infarction
Chronic microvascular disease Reduced medullary blood flow
Other Factors: NSAIDs Narcotics Chelating agents Hypovolemia Infection Rhabdomyolysis
AND/OR
Tubular damage: (e.g., direct tubular toxicity, ATN, interstitial nephritis
Increased local hypoxia
Tubulointerstitial damage
Urinary concentrating and acidification defects
Incomplete distal RTA
Prostaglandin release
Vasodilation
Increased renal blood flow
Elevated GFR
Proteinuria Glomerulosclerosis
CHRONIC KIDNEY DISEASE

Fig. 2 Pathophysiology of sickle cell nephropathy. Flow diagram depicts the pathways by which renal abnormalities develop as sequelae of the two primary pathophysiologic processes in SCD (vaso-occlusion and hemolysis) or other factors (such as medications), each of which may lead to diminished renal function and chronic kidney disease. *GFR* glomerular filtration rate, *RTA* renal tubular acidosis, *NSAIDs* nonsteroidal anti-inflammatory drugs

ETA antagonist improves kidney function and reduces injury, especially in combination with hydroxyurea (HU) therapy. Whether ETA blockers, which are now being studied in clinical trials for a variety of proteinuric kidney diseases, will have similar effects on SCD patients has yet to be determined.

Glomerular Pathology in SCD

A spectrum of glomerular pathologies has been reported in a renal biopsy series of SCD patients with proteinuria [3, 6]. Four main glomerular pathologies have been associated with SCN: (1) glomerular hypertrophy without overt sclerosis; (2) focal segmental glomerulosclerosis (FSGS) and its variants (such as collapsing FSGS); (3) membranoproliferative glomerulonephritis (MPGN); and (4) thrombotic microangiopathy (TMA). Although FSGS was the most common finding in one adult series [6], in a biopsy cohort of 36 children aged 4–19 years with SCD, mesangial hypertrophy was the most common finding (75% of patients) followed by FSGS (30%), MPGN (16%), and TMA (2%) [7]. In the past, the term “sickle cell glomerulopathy” was used to describe the MPGN-like pathology, but more recently the term has been applied to FSGS. Given the variable use of this term, it is more appropriate to describe the specific pathology rather than using the nonspecific term “glomerulopathy.”

Tubulointerstitial Disease

Both renal ischemia and hemolysis contribute to the pathogenesis of SCN [3, 4]. Several factors make the renal medulla susceptible to injury in SCD, ultimately resulting in distal nephron dysfunction and damage. The relative hypoxic and acidotic environment of the renal medulla makes it particularly prone to sickling of red blood cells that traverse the medullary vasculature. The resultant focal vascular occlusion causes chronically reduced blood flow. Red cell sickling also leads to vaso-occlusion within the vasa recta, resulting in vessel damage. Chronic and acute vasocontriction results in endothelial injury, which causes release of pro-inflammatory cytokines. Animal and human data suggest that ischemia-reperfusion injury also contributes to disease pathogenesis in multiple organs, including the kidney [8]. Hemolysis also induces tubulointerstitial injury by release of free plasma hemoglobin, which is readily filtered and taken up by renal tubule cells, resulting in iron accumulation [4]. As with ischemia, hemolysis also induces a marked inflammatory response, resulting in upregulation of inflammatory and profibrotic cytokines.

Defective Urinary Concentrating Mechanisms

The most common renal complication in SCD patients is impaired urinary concentrating ability (hyposthenuria). Urinary diluting mechanisms are generally intact. Progressive loss of deep juxtamedullary nephrons with age was once thought to be the primary mechanism for hyposthenuria. However, more recent data from the BABY HUG study, a multicenter randomized control trial of hydroxyurea (HU) in young children, show that hyposthenuria occurs at an early age and is somewhat correctable with administration of HU [2, 9]. The mechanism for this early hyposthenuria remains undefined. However, adults with SCD do not show similar improvement in urinary concentration with initiation of HU, suggesting that nephron loss and tubulointerstitial damage eventually contribute to the pathogenesis.

Alterations in Potassium and Acid-Base Homeostasis

SCD patients may have altered potassium handling due to distal nephron dysfunction, but those with intact kidney function typically do not develop hyperkalemia [3]. Hyperkalemia may become evident, however, when patients are exposed to factors that may impact potassium secretion in the kidney, such as volume depletion or medications, including angiotensin-converting enzyme inhibitors (ACEIs). Impaired acid-base hemostasis has also been reported in SCD and can occur by several mechanisms. Urinary acidification requires intact distal nephron function, which can be compromised in situations of medullary ischemia in SCD. Ammoniagenesis (renal cell metabolism of glutamine to $NH4^+$ and HCO_3^-) may also be impaired in patients with SCD, especially those treated with NSAIDs. Although impaired responsiveness to both acid and potassium loads suggests a distal renal tubular acidosis (RTA), patients with SCD without CKD have typically been reported to have normal serum bicarbonate levels [3]. Two larger, more recent studies, however, demonstrated that mild metabolic acidosis may be more common than previously thought [10, 11]. Correlation of metabolic acidosis and markers of hemolysis suggest that even a relatively mild acidosis occurring as the result of tubular dysfunction in SCD patients could contribute to worsening hemolysis by increasing sickling and promoting red cell destruction.

Papillary Necrosis

Hematuria appears to result from red cell sickling in the medulla with subsequent vascular obstruction and red cell extravasation. Pathologically, papillary necrosis (PN) manifests as intact collecting ducts amid diffuse areas of fibrosis [12]. There is also evidence of repeated, small focal infarctions of the papilla, which ultimately affect local circulation.

Clinical Features and Treatment of SCN

Although the numerous renal manifestations of SCN detailed in this chapter have been well documented in the literature (hyposthenuria, hematuria, impaired urinary potassium excretion and acidification, glomerular hyperfiltration and tubular dysfunction, medullary carcinoma, and CKD), most, unfortunately, are without specific effective therapies or clear prognoses. There are, however, several areas in which expert recommendations about kidney disease assessment and management have been published [13]. In addition, several therapeutic trials are underway or have been completed that could significantly impact the progression of kidney disease (available at clinicaltrials.gov).

Glomerular Disease

Hyperfiltration

As reported by the BABY HUG study, the majority of children with SCD manifest an elevated GFR, consistent with hyperfiltration, as early as 9 months of age [2]. Hyperfiltration often persists through childhood into adulthood. In the HUSTLE study, a prospective study of the long-term effects of HU in 23 children with a median age of 7.5 years, over 80% of the children had a measured GFR >1 SD above the normal for age [14]. A series of over 400 adults with SCD and a median age of 30 years reported that 49% of subjects had hyperfiltration using a definition of estimated GFR (eGFR) >130 mL/min/1.73 m^2 for women and >140 mL/min/1.73 m^2 for men [15]. Treatment with hydroxyurea (HU) did not affect hyperfiltration in infants in the BABY HUG trial [9] but did lessen hyperfiltration (GFR measured by (99m)Tc-DTPA decreased from 167 ± 46 to 145 ± 27 mL/min/1.73 m^2 ($P = 0.016$)) in older children after 3 years in the HUSTLE study [14]. This decrease in GFR correlated with an increase in fetal hemoglobin and a decrease in lactate dehydrogenase.

Albuminuria

Hyperfiltration has been identified as a risk factor for developing albuminuria and CKD in multiple kidney diseases, including SCN [16, 17]. Although the majority of children with SCD have an elevated GFR consistent with hyperfiltration, only a subset will develop significant albuminuria. Microalbuminuria (MA), which is typically defined as urinary albumin/creatinine ratio of 30–300 mg/g creatinine, is a potential early sign of glomerular damage and may predict progression to clinically significant CKD. Up to 20% of children with SCD demonstrate MA on routine urine screening [18, 19]. Twenty-six percent of a cohort of 303 pediatric and adult patients with SS disease (mean age 21 years) exhibited MA [20]. The prevalence of MA in studies of adults with SCD is even higher, ranging from 30% to 60% depending on the population studied [20, 21]. In addition to hyperfiltration, severity of anemia in SCD and the presence of hemolysis have also been identified as important risk factors for albuminuria [11, 22, 23] in both adult and pediatric SCD, although some studies in adults have not found such associations [21, 24].

Expert consensus guidelines recommend yearly albuminuria screening of patients ages 10 years and older, although the evidence to support this recommendation is not strong [13]. The issue of screening for MA is complicated by the fact that MA in SCD can regress and remain unchanged in some patients. In a retrospective study of 373 children with SCD, 45 (12%) had MA at baseline, but over the 5-year course of the study, 24 patients developed new MA and 24 patients showed normalization of MA [19]. In a study of 175 pediatric and young adult SCD patients with serial MA measurements, 26% had baseline albuminuria, of whom approximately half developed persistent albuminuria [20]. Taken as a whole, these studies demonstrate that MA precedes development of persistent albuminuria in a subset of SCD patients but may also regress, making it a relatively insensitive biomarker for kidney disease progression in children.

Macroalbuminuria (>300 mg/g creatinine), also termed overt proteinuria, is less common, especially in children. In one study of more than 400 children with SCD, overt proteinuria (defined as urine dipstick ≥1+ for protein) was documented in 6.2% of children and 12% of adolescents [22]. Macroalbuminuria is reported to occur in about 26% of adults with HgbSS disease and 10% of those with other sickle cell related disorders [21]. Once macroalbuminuria develops, it invariably persists [20].

Several studies have shown a reduction in albuminuria in pediatric and adult patients taking HU [25, 26]. The use of ACEI in adult patients with albuminuria with or without hypertension is recommended by expert consensus [13]. Despite these benefits, it is less clear if ACEI use produces similar long-term benefits in children with albuminuria, especially those with MA.

Hypertension

Despite the presence of multiple mechanisms by which the kidney can be affected by SCD, hypertension has been thought to be relatively uncommon, and SCD patients often have been reported to have low to normal blood pressures [27, 28]. Emerging data, however, suggest that hypertension in SCD is more common than previously appreciated, including in children. Elevated in-office blood pressures occur in 8–10% in children with SCD [29, 30]. A study of 38 asymptomatic children with SCD who underwent ambulatory blood pressure monitoring (ABPM) found that approximately 40% met criteria for ambulatory hypertension [30]. Importantly, approximately 30% of patients studied demonstrated masked hypertension, which, by definition, would be missed on routine blood pressure readings during office or study visits. While the reported differences in rates of hypertension may reflect variations in the nutritional status, body mass index, and SCD severity of the patient population, the methodology for assessing blood pressure may also play a significant role. The high prevalence of masked hypertension suggests that clinicians should have a low threshold for performing ABPM on patients with SCD, especially those with evidence of renal involvement, such as albuminuria.

Children with SCD and elevated blood pressure may be at higher risk for development of target organ damage. In the Silent Cerebral Infarct Multicenter Clinical Trial, a large multicenter trial of 814 children with no history of stroke or seizure, higher baseline systolic blood pressure was found to be a risk factor for silent cerebral infarction [31]. The prevalence of left ventricular hypertrophy (LVH) has been reported to be as high as 46% in children with SCD but does not correlate with mortality [32]. The finding of high rates of LVH in SCD patients, however, is confounded by the fact that LVH can develop as the result of chronic anemia. Thus, it may be difficult to determine if LVH is related to hypertension, anemia, or both.

As with other forms of CKD, effective control of hypertension, when identified, is likely to slow the progression of CKD in SCN. Optimal blood pressure targets have not yet been defined for SCN but presumably are similar to those of other forms of CKD. While SCD patients can generally be treated with standard approaches, there are disease-specific considerations in the choice of antihypertensive medications. Because dehydration can precipitate vaso-occlusive events and SCD patients often have hyposthenuria, diuretic agents should be avoided in these patients. Angiotensin-converting enzyme inhibitors are frequently utilized in proteinuric renal disease, including SCN. Patients receiving these medications, however, may require additional and more frequent monitoring for increases in serum creatinine and hyperkalemia, particularly during dehydration states or acute pain crises when NSAID use is common.

Tubulointerstitial Disease

Hyposthenuria, Enuresis, and Nocturia

As noted previously, the inability to form a concentrated urine (hyposthenuria) is an early finding in SCD that typically manifests as polyuria. In the BABY HUG study, approximately 20% of infants had hyposthenuria [2, 9]. Of those able to form a concentrated urine, only 38% had a urine osmolality >500 mOsm/kg H_2O. Hyposthenuria can also cause enuresis and nocturia. Enuresis rates in children with SCD ages 5–10 years have been reported to be as high as 40–50% [33]. Enuresis decreases with age, but up to 9% of adults ages 18–20 years will have persistent symptoms. Nocturia is also common in children and adults with SCD, occurring in almost 80% of patients [33]. As a result of defective urinary concentrating ability, patients with SCD may be more susceptible to intravascular volume depletion, which, in turn, can precipitate acute vaso-occlusive events. Maintaining adequate hydration, therefore, is paramount, particularly in settings such as strenuous physical activity and extremes of temperature. For patients with nocturnal enuresis, standard interventions such as avoiding fluids before bedtime may have varying success given the presence of polyuria. Data on the use of desmopressin (DDAVP) for the treatment of nocturnal enuresis in children with SCD are limited to one study of ten SCD patients treated with DDAVP of whom 60% showed improvement or resolution in their enuresis [34].

Hematuria and Papillary Necrosis

Hematuria is a common renal finding in SCD and can occur at any age. Both microscopic hematuria and hemoglobinuria may be present. Papillary necrosis (PN), a more severe manifestation of medullary ischemia, is reported to occur in 15–36% of patients with SCD [35]. Many patients with PN may be asymptomatic. Some, however, can present with acute onset of renal colic, gross hematuria with clots, and acute kidney injury (AKI) with or without urinary tract obstruction. PN can also follow a more protracted course with recurrent episodes of gross hematuria and/or urinary tract infection [12]. The preferred method for diagnosing PN is computerized tomography (CT), which demonstrates the characteristic circumscribed, yet often poorly marginated areas of diminished enhancement in the medullary pyramids, indicating early ischemic changes, as well as clefts originating from the calices [36]. Renal ultrasonography may demonstrate evidence of papillary necrosis on occasion but is generally not as useful for establishing the diagnosis. Due to its self-limiting nature, the management of gross hematuria is usually conservative and limited to maintaining adequate hydration, bed rest, pain relief, and antibiotics if necessary. Additional interventions directed at coagulation and/or anti-fibrinolytic actions studied in small case series include epsilon aminocaproic acid (EACA) and tranexamic acid.

Medullary Carcinoma

Renal medullary carcinoma (RMC) is a rare, aggressive neoplasm that is reported to occur almost exclusively in patients with SCD or SCT [37]. Affected patients generally present with gross hematuria or flank pain. Metastatic disease is often present commonly at diagnosis. The pathogenesis of this malignancy is poorly understood. The prognosis, even with chemotherapy, is extremely poor.

Acute Kidney Injury (AKI)

AKI has been increasingly recognized as an important occurrence in hospitalized children, including those admitted for SCD-related complications. AKI is reported to occur in 8% of SCD children hospitalized for acute chest syndrome [38] and 17% of patients admitted for vaso-occlusive crisis [39]. AKI in SCD patients is associated with prolonged length of stay and increased morbidity and resource utilization [39, 40]. Multiple risk factors for AKI development in SCD have been identified, including older age, history of hypertension, hematuria or CKD, lower hemoglobin level, increased hemolysis, NSAID use, and rhabdomyolysis [4, 39–41]. Angiotensin-converting enzyme inhibitors and the presence of dehydration may also increase AKI risk. The use of HU may decrease the risk of AKI, presumably by improving hemoglobin levels and decreasing the severity of red blood cell sickling [40].

Chronic Kidney Disease (CKD)

Although rates of CKD in patients with SCD vary based on the definition utilized and population studied (including the proportion of more versus less severe SCD genotypes), up to 20% of adults with SCD have CKD [13, 15]. In children, 8–12% have been reported as having CKD Stage 2 or higher [18, 29]. Patients with SCD who develop CKD may manifest complications similar to those of patients with other forms of CKD, such as electrolyte disturbances, edema, hypertension, progressive anemia, and mineral bone disorder. These are generally managed similarly to other forms of CKD. There are, however, several important considerations in CKD management of SCD related to assessments of kidney function, mechanisms and treatment of anemia, and management of ESKD that are highlighted below.

Renal Function Measurements and Imaging Findings

Hyperfiltration, coupled with increased tubular secretion of creatinine, tends to cause low serum creatinine in SCD patients. While hyperfiltration may reflect an actual increase in GFR, increased tubular creatinine secretion would be expected to result in overestimation of actual kidney function. Thus, one of the challenges in accurately determining the degree of renal dysfunction in SCN is identifying a reliable GFR marker that can be followed over time. The BABY HUG trial reported that eGFR (bedside Schwartz formula) correlated only weakly with measured GFR [2]. It should be noted, however, that the study involved infants and young children, the majority of whom had elevated GFRs. Whether the same finding holds true for older children and/or those with decreased GFRs has not been determined. Several adult studies have assessed the utility of eGFR equations compared to measured GFR values and found that the CKD-EPI (Chronic Kidney Disease Epidemiology Collaboration) equation showed the best correlation with measured GFRs [42, 43]. Renal biopsy is invasive, has associated risks, and is typically only performed in patients with significant proteinuria.

Renal ultrasonography abnormalities are not uncommon in SCD and may include increased echogenicity, particularly within the medulla, and bilaterally enlarged kidneys [44]. Magnetic resonance imaging (MRI) has also been studied as a potential biomarker for early CKD. MRI with diffusion tensor imaging (DTI) to assess renal microstructure and T2 relaxometry to assess iron deposition has been piloted in a small study [45]. When compared to healthy controls, SCD patients demonstrated MRI changes suggestive of altered medullary microstructure and increased iron deposition. These novel imaging techniques may be able to detect kidney changes before they are clinically apparent (e.g., reduced eGFR).

Anemia in SCD Patients with CKD

In the face of persistent anemia, SCD patients, even those with CKD, typically have elevated erythropoietin (EPO) levels, although not at the levels that would be expected for the degree of anemia. One explanation for the suboptimal EPO levels is the right-shifted hemoglobin-oxygen dissociation curve seen in this patient population. Because sickle hemoglobin has less affinity for oxygen, this translates into better oxygen delivery to target tissues, thereby suppressing the release of EPO. As kidney function declines, this suboptimal EPO production becomes more problematic. As a result, patients with SCD and CKD may require much higher doses of erythropoietin-stimulating agents (ESAs) compared to other patients with CKD to achieve acceptable hemoglobin levels.

Renal Replacement Therapy

Children with SCN who progress to ESKD can be treated with either hemodialysis or peritoneal dialysis using the same selection criteria that are used for pediatric ESKD from other causes. Dialysis management of ESKD in SCN is similar to that of other causes of ESKD [46], with the exception that patients with SCN typically require substantially higher doses of EPO and are more likely to require multiple blood transfusions [47].

Successful kidney transplantation in SCN has been well documented [48, 49], including in a small number of pediatric patients [50]. As is done commonly with other major surgical procedures in SCD patients, preoperative transfusion to decrease the proportion of sickle hemoglobin is recommended for patients undergoing kidney transplantation. In addition, several unique complications have been described. Patients may experience a resumption of frequent vaso-occlusive events, which are presumed to be related to an increase in whole blood viscosity accompanying a higher hemoglobin level [51]. Patients with SCD may benefit from exchange transfusions after kidney transplantation, particularly when hemoglobin levels are elevated.

Prognosis

Despite the multiple mechanisms by which SCD could result in kidney damage and progressive CKD, rates of ESKD in patients with SCD are relatively low. In adults, approximately 2–4% with SCD will progress to ESKD [13, 15]. ESKD in children with SCD is rare. The United States Renal Data Survey (USRDS) database reported that 0.2% of pediatric ESKD cases were attributed to SCD between 2003 and 2012 [52]. Given that patients with SCD are surviving longer due to improved medical care and the increased use of HU as well as newer therapeutics, it is anticipated that ESKD rates will rise. Unfortunately, CKD is an important contributor to decreased survival, accounting for 16–18% of mortality in adults with SCD [4].

Risk Factors for CKD Progression

Hospitalizations for vaso-occlusive crisis have been identified as the most important predictor of progression to ESKD and mortality in patients with SCD [53]. In contrast, in those with biopsy-confirmed glomerular disease, the specific renal pathology (e.g., FSGS vs. MPGN) does not appear to impact overall renal survival [6]. There are several other factors that have been identified as potential risk factors for CKD progression that are discussed below.

Albuminuria

As noted previously, microalbuminuria is a common finding in children and adults with SCD, although it can regress, particularly in children. In adult patients, persistent microalbuminuria has been associated with more rapid decline in eGFR [20]. However, the association of eGFR decline and MA has not been consistently demonstrated in children. In contrast, the prognosis for pediatric and adult patients with SCD and overt proteinuria is poor, with a significant proportion progressing to clinically significant CKD [4, 14].

AKI

AKI, especially severe or repeated AKI episodes, has emerged as an important risk factor for development and progression of CKD in children [54, 55]. As noted above, patients with SCD are at high risk for development of AKI due to multiple factors. While unique associations between AKI and development of CKD in patients with SCD have not been established, it is likely that AKI contributes to CKD in this population as it does in other pediatric and adult populations.

Hemolysis

While chronic vaso-occlusion causes renal damage by multiple mechanisms that likely increase the risk of CKD, chronic hemolysis has also been implicated as a risk factor for development and progression of CKD. In one larger study that examined the relationship between hemolytic markers and hemoglobinuria, both were independently associated with CKD and its progression and were stronger predictors of CKD than indirect hemolytic markers (LDH, reticulocyte count), suggesting that release of cell-free hemoglobin may be an important mediator of renal damage leading to CKD [56].

Genetic Factors

As with other SCD complications, renal dysfunction is more common and more likely to show decline in those patients with SS and Sβ^0thalassemia genotypes [15, 21, 57]. Genetically determined levels of fetal hemoglobin may also impact development and progression of CKD. Patients with the lowest fetal hemoglobin levels are more likely to develop CKD and other SCD complications, whereas those with elevated fetal hemoglobin levels are protected from development of CKD [58].

A growing body of literature has demonstrated the association of apolipoprotein L1 (APOL1) gene risk variants with a significantly increased risk of developing CKD in those of African ancestry [59]. Inheritance of one of the risk alleles (named G1 and G2) is thought to provide protection from trypanosomal disease and, therefore, convey a survival advantage in Africa. Inheritance of two risk alleles, however, is associated with a significantly increased risk of developing albuminuria, CKD, and ESKD [59]. Recent studies in adults suggest that APOL1 risk genotypes are associated with increased risk of CKD in patients with SCD as well [56, 60]. A study of children enrolled in the Sickle Cell Clinical Research and Intervention Program (SCCRIP) study, a lifespan cohort study examining progression of SCD from infancy to adulthood, found that those who carried two APOL1 risk alleles developed albuminuria at a younger age compared to those who had zero or one risk allele [61]. The clinical utility of performing APOL1 genotyping of African Americans in various settings, including kidney transplantation, is the subject of active investigation.

Dialysis and Renal Transplantation Outcomes

Because ESKD due to SCN is relatively rare in the pediatric population, data on dialysis outcomes in children are lacking. Dialysis outcomes for adults with SCN are poor: adults with SCD have higher mortality rates than their non-SCD counterparts [46, 62]. Given the rarity of ESKD in children with SCN, as well as the overall poor outcomes for adult dialysis patients compared to pediatric dialysis patients, it is difficult to know whether children with SCN have similar dialysis-associated mortality.

As with dialysis outcomes, data on kidney transplantation outcomes in children with SCN are limited. One study of 9 children from the NAPRTCS database reported graft survival rates of 89% at 1 year and 71% at 2 years [50]. Of the three patients whose grafts eventually failed, one had acute rejection, one died from an unrelated cause, and one had chronic rejection. Early rejection was frequent and was attributed to inadequate immunosuppression (seen in five of the six episodes). In adult studies, the outcomes of kidney transplantation in SCD patients show considerable variability [63]. In the largest published series to date, age-matched African American kidney transplant recipients with ESKD due to SCN ($n = 82$) were compared to all other causes of ESKD ($n = 22{,}565$) [48]. Rates of delayed graft function and acute rejection were similar in the two groups as was 1-year deceased donor graft survival. However, the 3-year deceased donor graft survival tended to be lower in the SCD group (48% vs. 60%) and the adjusted 3-year risk of graft loss was significantly greater. Adjusted mortality risk in the SCD group was also higher both at 1 year and at 3 years. Two smaller, more recent studies provide additional insight into kidney transplantation outcomes. One study of 36 SCD patients reported postoperative surgical complications in 25% of patients, high rates of CMV and bacterial infections, and a higher mortality rate than non-SCD patients [49]. A study of 34 SCD patients of whom 20 received regular exchange blood transfusions (EBT) also reported worse overall patient and graft survival rates, including higher rejection rates, compared to non-SCD patients. SCD patients who received EBT had lower rates of acute rejection compared to those who did not receive EBT [64]. Thus, although complication rates are higher in both pediatric and adult patients with SCD who undergo renal transplantation compared to patients without SCD, kidney transplantation appears to be the preferred treatment for ESKD in this population, particularly given the significant mortality associated with long-term dialysis therapy.

Sickle Cell Trait

Sickle cell trait (SCT) is defined as inheritance of one copy of the HgbS mutation. It is estimated that SCT affects 1 in 12 African Americans and almost 300 million people worldwide. Although SCT was previously thought to be a benign condition, more recent data suggest that it may be more detrimental than previously appreciated. Hematuria and PN are more common in SCT compared to SCD. This is most likely due to the increased prevalence of SCT as compared to SCD in the general population. It could also be due to the higher hematocrit of people with SCT, which could predispose them to red cell sludging in the kidneys. Medullary renal carcinoma also occurs in patients with SCT. Of additional concern is the growing body of data demonstrating an increased risk for ESKD among those with SCT compared to African Americans who are not carriers. The eGFR of individuals with SCT has been reported to decline significantly faster when compared to healthy reference patients [65]. An observational study of over 1200 patients from 5 US population-based, prospective cohort studies confirmed the high prevalence of SCT among patients with CKD. In that study, SCT was associated with an increased risk of CKD, decline in eGFR, and albuminuria. These associations were independent of APOL1 risk variants and suggest that SCT may be an additional genetic factor contributing to the overall increased risk of CKD in African Americans compared with other populations [66]. In a subsequent study of almost 10,000 self-reported US black patients, the ESKD incidence rate for those with SCT was twice that of non-SCT black patients [67].

Conclusions

Patients with SCD are at risk for the development of numerous renal complications, collectively termed SCN. Given the potential for significant morbidity and mortality associated with SCN, it is imperative that patients be monitored routinely for indications of renal involvement, such as hypertension and albuminuria. Particular attention should be paid to renal function in the context of patients treated with NSAIDs, especially if they are also receiving ACEI therapy. Serum creatinine values and eGFR should be interpreted in the context of known hyperfiltration, and a “normal” eGFR may, in fact, suggest significant decline in function. Continued research is imperative to better elucidate the pathophysiology underlying SCN as well as the contribution of other genetic and/or environmental factors that could be therapeutic targets.

Abstract

Diabetic kidney disease (DKD) is a serious complication of type 1 diabetes (T1D) and represents a major cause of end stage renal disease (ESRD) and cardiovascular morbidity and mortality. DKD occurs due to interactions between several factors, including hyperglycemia, dyslipidemia, hypertension, oxidative stress, advanced glycated end products, and genetic factors, which induce progressive functional and structural changes in the kidney. Clinically, DKD is characterized by increasing albuminuria, progressive decline in glomerular filtration rate, and elevated blood pressure, which without any treatment progress towards ESRD. Advanced stages of DKD are rare among children and adolescents with T1D, whereas early

stages, such as hyperfiltration and moderately increased albuminuria, can be common. Several risk factors contribute to the development of DKD, the main being hyperglycemia, high blood pressure, dyslipidemia, diabetes duration, age at diagnosis, female gender, and puberty, along with genetic and environmental factors. Albuminuria, formerly known as microalbuminuria, is considered the earliest clinical manifestation of DKD and is the basis for screening for this complication. Screening for DKD is recommended starting at age 10–12 years and repeated annually. During adolescence, the primary focus of management the risk of DKD is improvement in glycemic control. Targeting additional risk factors, such as hypertension, dyslipidemia, and obesity, is also recommended. When persistent albuminuria is detected, treatment with angiotensin-converting enzyme inhibitors is indicated. There is still a need for new biomarkers to facilitate early detection of subclinical stages of DKD and to support the implementation of intervention strategies, to ultimately reduce the burden of DKD.

Introduction

Type 1 diabetes (T1D) is a common chronic condition affecting approximately 1.1 million children and adolescents (age <19 years) worldwide, with a growing incidence by 3–4% per year [1]. Individuals with T1D experience increased morbidity and a 2- to 4-fold higher mortality compared to the general population [2, 3]. A young age at the onset of T1D is associated with less favorable outcomes, with life expectancy being reduced by 14–17 years in individuals diagnosed before the age of 10 compared to 9–10 years in those diagnosed after the age of 20 [3]. The long-term health burden of T1D is largely due to the associated microvascular and macrovascular complications [2].

Diabetes kidney disease (DKD), also known as diabetic nephropathy, is one of the most common microvascular complications, affecting around 25–30% individuals with T1D [4, 5]. DKD represents a major cause of end-stage renal disease (ESRD), constituting 10–67% of all cases, and compounds the risks of cardiovascular disease and overall mortality from T1D [4, 5]. In individuals with T1D, DKD is usually a clinical diagnosis based on the presence of albuminuria and/or reduced glomerular filtration rate (GFR), in the absence of signs or symptoms of other primary causes of kidney damage [6, 7]. Other potential forms of kidney disease can occur in the context of diabetes, such as acute kidney injury, often secondary to diabetic ketoacidosis in youth with T1D, and ischemic nephropathy from vascular disease and hypertensive nephrosclerosis mostly in older people with T1D [7].

Natural History of Diabetic Kidney Disease

DKD manifests with the classic triad of increased urinary albumin excretion (albuminuria), renal function decline, and hypertension and is traditionally described as occurring through five sequential stages [8] (Fig. 1). The first stage is generally a "hyperfiltration phase," characterized by increases in GFR, capillary glomerular pressure, and kidney size, without albuminuria or hypertension. The second stage, classically defined as the "silent phase," manifests with progressive increases in urinary albumin excretion that remain within the normal range, and with normal or increased GFR. Structural changes, including basement membrane thickening and mesangial expansion, are observed during this phase [9]. The third stage is characterized by more substantial increases in albumin excretion up to 30–300 mg/day or 20–200 μg/min, referred to as "moderately increased albuminuria" or previously as "microalbuminuria" [8]. With persistent albuminuria, widespread advanced renal structural lesions are observed [9]. GFR during this phase can be increased, normal, or reduced, and hypertension is often present. The fourth

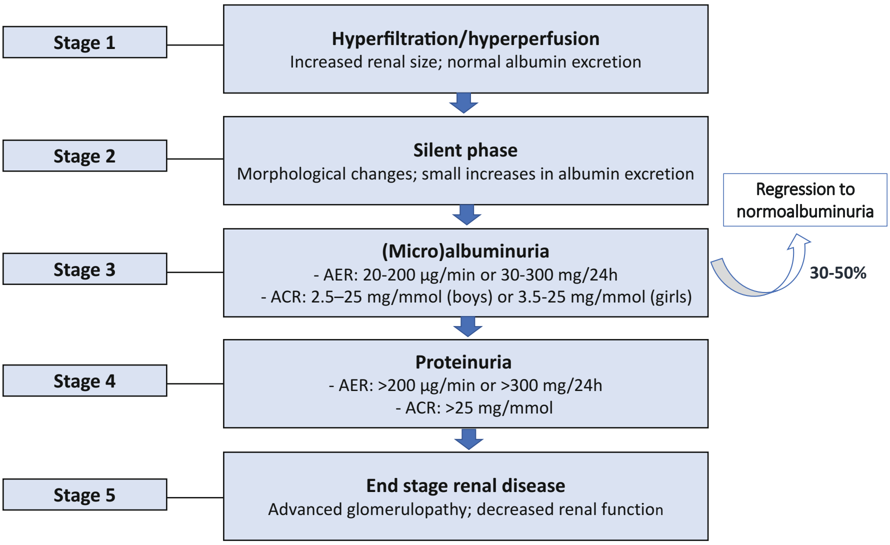
stage, occurring 10–15 years after T1D onset, is characterized by overt proteinuria (>300 mg/day) (previously referred as “macroalbuminuria”), decreased GFR (<60 ml/min/1.73m^2), and sustained hypertension. If left untreated, this stage will progress towards renal failure [8]. The fifth and final stage is characterized by uremia and ESRD. At this stage, patients often require renal replacement therapy and/or renal transplantation with simultaneous pancreas transplantation or pancreas-after-kidney transplantation [8].

Over recent decades, there has been a paradigm shift in the natural history of DKD, with the emergence of new concepts. One is the phenomenon of “regression to normoalbuminuria,” which can occur in 30–50% of adults and youth with T1D, and is positively influenced by better glycemic control and lipid and blood pressure profiles [10–12]. This concept has challenged the classical view of microalbuminuria as an irreversible predictor of progression to proteinuria and decline in renal function [11]. Recent data have also shown that in children and adolescents, as in adults, progressive increases in albumin excretion, even remaining within the normal range, can be detected soon after diagnosis and are associated with a higher risk for the development of DKD as well as retinopathy and cardiovascular complications [13]. These findings suggest that albumin excretion should be considered as a predictive biomarker for renal and cardiovascular disease [14]. In addition, data from adults with T1D have shown a “nonalbuminuric DKD” phenotype, whereby early declines in GFR can occur in the absence of albuminuria, which might reflect different renal structural changes [5]. To this point, however, there are no definitive data that this phenotype is found in youth with T1D.

DKD Manifestations in Youth with T1D

Advanced stages of DKD, such as proteinuria, GFR <60 ml/min, or ESRD, are uncommon among youth with T1D [15]. However, early asymptomatic stages, reflecting subclinical renal functional and structural changes, may manifest as early as 1.5–5.0 years after the onset of T1D and are common particularly during adolescence [16, 17] (Fig. 2). These subclinical manifestations include increases in urinary albumin excretion up to the range of albuminuria and increased GFR (hyperfiltration) [16–19]. In adolescents with T1D, rates of hyperfiltration range from 10% to 50% and when present is an independent predictor of albuminuria and later decline in renal function [18–20]. Hyperfiltration, which is often associated with increased renal size, reflects the effect of hyperglycemia on renal hemodynamics, as well as pubertal physical and hormonal changes [18, 19].



Stage 1
Hyperfiltration/hyperperfusion
Increased renal size; normal albumin excretion
Stage 2
Silent phase
Morphological changes; small increases in albumin excretion
Stage 3
(Micro)albuminuria
- AER: 20-200 µg/min or 30-300 mg/24h
- ACR: 2.5–25 mg/mmol (boys) or 3.5-25 mg/mmol (girls)
Regression to normoalbuminuria
30-50%
Stage 4
Proteinuria
- AER: >200 µg/min or >300 mg/24h
- ACR: >25 mg/mmol
Stage 5
End stage renal disease
Advanced glomerulopathy; decreased renal function

Fig. 2 Natural history of diabetic kidney disease

Albuminuria (or microalbuminuria) is the earliest stage of clinical DKD, and its persistence is predictive of progression to overt proteinuria and cardiovascular sequelae [21]. In people with childhood-onset T1D, microalbuminuria is often detected during puberty, with a cumulative prevalence of around 5–26% at 5–10 years after diagnosis of diabetes, and up to 50% by 19 years after diagnosis of diabetes [10]; in contrast adults with 19 or more years of diabetes have a microalbuminuria prevalence of only 34% [10]. During adolescence, microalbuminuria can be transient or intermittent, with return into the normal range, after 3–10 years, in 30–50% of cases [10, 12]. Although these data are encouraging, transient or intermittent microalbuminuria can become persistent with longer follow-up, likely related to permanent underlining renal structural abnormalities [9, 10]. Therefore, renal function should be repeatedly monitored in any patient developing microalbuminuria. The rate of progression of microalbuminuria to proteinuria appears to be similar between adults and youth with T1D, although proteinuria occurs at an earlier age in younger patients with T1D. In the Oxford Regional Prospective Study cohort, the cumulative prevalence of proteinuria was 13.9% for youth and 14.6% in adults by 19 years after diagnosis of T1D [10].

Pathogenesis

Glomerular basement membrane thickening and mesangial expansion are prominent glomerular lesions in DKD [9, 22]. The pathophysiologic changes in DKD include cellular and extracellular derangements in both glomerular and tubulo-interstitial compartments, including hyperplasia or hypertrophy of various cell types of the glomerulus and tubules, thickening of glomerular and tubular basement membranes, and expansion of the tubulointerstitium and mesangium [9, 22]. Other changes include hyalinization of arterioles and thickening of branches of intrarenal arteries. Foot process effacement and decreased podocyte number and/or density per glomerulus are also common [9, 22]. Diabetic tubulopathy, which may precede or occur concurrently with glomerular changes, is characterized by a variety of structural and functional alterations including tubuloepithelial cell hypertrophy, tubular basement membrane thickening, expansion of the interstitial space with infiltration of various cell types (myofibroblasts and macrophages), epithelial-mesenchymal transition, and glycogen accumulation [9, 22].

The pathogenesis of DKD is incompletely understood, but it likely results from an interplay between several metabolic and hemodynamic factors, which occur as a consequence of hyperglycemia, hypertension, dyslipidemia, genetic predisposing factors, and other environmental exposures [9, 22] (Fig. 2). Hyperglycemia is crucial for the initiation and progression of diabetes-induced renal injury, contributing to abnormal cellular homeostasis and changes in glomerular blood flow and/or vascular permeability, along with tubular and mesangial changes [9, 22]. Hyperglycemia triggers/alters many signaling cascades including activation of diacylglycerol-protein kinase C, polyol and hexosamine pathways; increased oxidative stress, advanced glycation end-products, subclinical inflammation and production of cytokines/growth factors; and dysregulation of the renin-angiotensin system (RAS) [23]. Overproduction of mitochondrial superoxide following hyperglycemia is likely the primary initiating mechanism leading to cellular redox imbalance and oxidative stress [23]. Inflammation, hypoxia, the complement system, and the klotho system also play an important role in the pathogenesis of DKD [22, 23].

Risk Factors

Adolescence is a critical period for the appearance of the first potentially reversible signs of DKD and other diabetes vascular complications [14, 17]. Several risk factors, both modifiable (glycemic control, hypertension, dyslipidemia, lifestyle) and nonmodifiable (diabetes duration, puberty, genes, constitutional factors), have been related to the development of DKD in youth with T1D [17, 24] (Fig. 1). The risk of complications is strongly related to duration of diabetes as DKD tends to reach a peak incidence after 15–20 years [24]. Age at diagnosis is another risk factor, with higher risk of early manifestations of renal disease as well as other vascular complications associated with an early age at the time of diagnosis [10]. Among youth with T1D, biological females have a higher risk of developing microalbuminuria than biological males, which contrasts with the higher risks in adult males [10]. The higher female risk for microalbuminuria may be due to worse glycemic control, higher insulin resistance, increased androgens levels, and lower insulin-like growth factor-1 (IGF-1) levels than in males [17].

Glycemic Control

Hyperglycemia is the major modifiable risk factor for DKD as well as for other vascular complications of T1D. Several observational studies and clinical trials have shown a strong association between glycated hemoglobin (HbA1c) and DKD in youth and adults with T1D [10, 25]. In clinical practice, measurements of HbA1c every 3 months are typically used to assess glycemic control in patients with T1D [26, 27]. Current guidelines from the International Society for Pediatric and Adolescent Diabetes (ISPAD), the American Diabetes Association (ADA), and other organizations recommend a target for HbA1c of <6.5–7% (48–53 mmol/mol), to decrease risk of DKD and other vascular complications [26, 27]. Recent data confirmed that, in youth with T1D, overall DKD risk substantially increases with an HbA1c above 7% (53 mmol/mol) and more advanced stages of DKD, such as proteinuria, are associated with HbA1c $>8.6\%$ (>70 mmol/mol) [28]. Optimal glycemic control is often difficult to achieve during adolescence, with data consistently demonstrating the highest HbA1c levels during this time of life [29] with only 20–30% adolescents achieving recommended HbA1c targets [14]. The increases in HbA1c during adolescence are attributed to poor adherence to diabetes self-management, eating disorders, and/or psychological problems [30]. Additional factors contributing to suboptimal glycemic control are insulin resistance and pubertal hormonal changes [30].

Other Risk Factors

In adolescents with T1D, several factors other than glycemic control, including pubertal growth, hormonal changes, and age-specific psychological issues, can contribute to the development of the early signs of DKD [17, 30]. Puberty is characterized by rapid renal growth and glomerular hyperfiltration, both of which exacerbates DKD risk, independently of glycemic control [19]. These changes in kidney structure and function may be linked to increased circulating growth hormone and decreased IGF-1 levels, which are both associated with a higher risk of microalbuminuria [17]. Cardiometabolic risk factors such as obesity, hypertension, dyslipidemia are common among adolescents with T1D and contribute to complication risks [31]. Abnormalities in blood pressure, including reduced nocturnal dipping and increased diastolic blood pressure, predict for adolescents who later develop microalbuminuria [26]. Youth with T1D also have a high prevalence of dyslipidemia, characterized by both qualitative and quantitative abnormalities in lipids and/or lipoproteins, both of which are associated with rates of urinary albumin excretion [26]. Obesity is common among youth with T1D (9–20%), and a high BMI is associated with increased rates of DKD [31, 32]. Lifestyle factors, such as smoking, alcohol, sedentary lifestyle, diet, and stress, can also increase risks of complications [31].

Emerging data also show associations between socioeconomic factors, such as lower education levels and household income, and greater risks of adverse renal outcomes [33].

Genetic factors also likely contribute to the risk of DKD, as studies show a 2–4 fold higher risk of developing DKD for a proband with a sibling that has DKD [34]. In addition, a family history of insulin resistance, hypertension, dyslipidemia, and/or cardiovascular disease is more common among adolescents with microalbuminuria than those without microalbuminuria [35].

Screening and Diagnosis

DKD as well as the other vascular complications of T1D are often asymptomatic during early stages, and once symptoms develop, disease progression may be harder to reverse [14, 26]. Therefore, identification of subjects at risk and screening for subclinical signs of complications is essential for the implementation of timely preventive and therapeutic strategies. International guidelines recommend screening for DKD starting at ages between 10 and 12 years. These recommendations are based on evidence suggesting that complications are rare in younger children [26]. Based on the ISPAD guidelines, screening should start at age 11 years with 2–5 years diabetes duration and repeated annually, with potential variation in the frequency based on the individual's risk profile [26].

Screening for DKD is focused on detection of increased albuminuria, which can be assessed with 24-hour or timed urine collections or as albumin-creatinine ratio (ACR) on a spot urine sample [26]. Assessing ACR in a spot urinary sample is the most common method used in clinical practice. First morning voided urine is preferable due to diurnal variations in albumin excretion and postural effects; however, if this is not possible, uniformity of timing for serial collections in the same individual should be employed [26]. When using ACR, values between 2.5 and 25 mg/mmol in males and 3.5 and 25 mg/mmol in females denote moderately increased albuminuria or microalbuminuria (different reference ranges are due to sex-related differences in creatinine excretion) [26]. On 24-hour urine samples, 20–200 μg/min or 30–300 mg/day represents microalbuminuria. Values above these limits for spot or 24 hour samples are diagnostic of proteinuria/macroalbuminuria [26].

Exercise, infections, fever, marked hyperglycemia, other types of kidney disease, and/or systemic inflammatory diseases can influence albumin excretion, and therefore, these factors need to be excluded when interpreting elevated albumin excretion. Confirmation of persistent albuminuria is based on high levels on serial samples (at least 2 abnormal values among 3 samples collected over a period of 3–6 months), since there is substantial within-subject variation in urinary albumin excretion. Regular longitudinal follow-up of albumin excretion is also important to identify patients with progressively small increases of urinary albumin excretion within the normal range, which might presage the development of microalbuminuria [14, 26].

Although urinary albumin excretion is generally the cornerstone for the diagnosis of DKD, identifying alterations in GFR may be important during the early and late stages of DKD. Presently, routine assessment of GFR is not typically included in pediatric guidelines [26]. In clinical research and practice, GFR is typically estimated by equations using endogenous filtration markers (serum creatinine and/or cystatin C) often adjusted for age, sex, and height. While many formulas using these endogenous filtration markers have been proposed in children and adolescents, no single equation has been specifically developed or validated in youth with T1D [20]. Most formulas to estimate eGFR are less accurate in the hyperfiltration range and therefore are not optimal to use in adolescents with T1D [20]. Improved methods to easily and accurately measure GFR as well as changes in renal function in both the normal and hyperfiltration range are therefore needed. Clinicians must also evaluate youth with T1D with apparent new renal disease for possible nondiabetic causes, as part of the diagnostic workout. An active urinary sediment (e.g., hematuria), rapidly increasing albuminuria or nephrotic syndrome, and/or a rapidly decreasing GFR suggests alternative and/or additional causes of kidney disease. For patients with these features, referral to a nephrologist for further workup, including the possibility of kidney biopsy, should be considered [6].

New Biomarkers

There is a growing interest in identifying new biomarkers which could replace GFR and ACR or improve their predictive value for the early identification of DKD and prediction of its progression [36–38]. Recent advancements in proteomics, metabolomics, and other "omics" have identified new potential biomarkers for DKD [38]. Newer DKD biomarkers identified to date include those in the following categories: glomerular and renal tubular biomarkers, cardiovascular biomarkers and inflammation-, oxidative stress-, and fibrosis-related biomarkers. A renal biomarker which has been largely investigated is cystatin C, a plasma protein produced by all nucleated cells, freely filtered by glomeruli and completely metabolized by proximal renal tubules, which has been associated with ESRD [36]. Several inflammatory biomarkers have been investigated in relation to DKD, including tumor necrosis factor receptors, orosomucoid, fibroblast growth factor-23, cytokines (IL-6, IL-10, INF-gamma, TNF-α), and growth/differentiation factor-*15*, YKL-40 [22, 36]. Proximal tubular proteins, such as urinary Kidney Injury Molecule-1, Neutrophil gelatinase-associated lipocalin, and liver-type fatty acid-binding protein, have been associated with a faster decline in GFR in individuals with T1D [22, 36]. Studies have also identified that cardiovascular disease biomarkers, such as high-sensitivity troponin T and N-terminal pro-B-type natriuretic peptide, can predict decline in renal function in T1D [22, 36]. Uric acid, a product of purine metabolism, has recently shown promise in predicting renal function impairment in individuals with T1D [36]. Urinary proteomics, a promising tool to identify biomarkers of DKD, has identified CDK273, a panel of 273 urinary biomarkers, that is associated with progression of albuminuria and loss of renal function in adults with diabetes [39]. Metabolomics has also been applied in the field of DKD and unveiled several metabolites including products of lipid metabolism, branched chain and aromatic amino acids, and citric acid cycle metabolites related to mitochondrial dysfunction that may predict for poor outcomes [22, 36]. To date, however, none of these promising new biomarkers have been integrated into clinical practice.

Prevention and Treatment

Glycemic Control

During adolescence, the primary focus for DKD risk management is on improvements in glycemic control [26, 27]. The benefits of achieving HbA1c targets (HbA1c <6.5–7.0% or <48–53 mmol/mol) to prevent vascular complications is supported by a large body of evidence, starting with the landmark Diabetes Control and Complications Trial and including more recent studies [25]. Multiple daily insulin injections and continuous subcutaneous insulin infusion (CSII) are the main treatment modalities in youth with T1D. Over the last several years, there have been significant advances in technology for the management of T1D, with the introduction of CSII and continuous glucose monitoring (CGM); more recently, automated insulin delivery systems or close loop systems (artificial pancreas), which combine real-time CGM with CSII and a control algorithm to direct automated insulin administration, have contributed to better glycemic control [40]. Use of CGM allows the evaluation of glucose variability, which has emerged as another potential target to prevent diabetes complications in adults with type 2 DM (to date scant data are available for T1D, particularly for the pediatric population). In addition, CGM data have shown the importance of time in range (TIR), defined as the percentage of time when glucose values are within an acceptable range (70–180 mg/dl or 3.9–10.0 mmol/l) [41] Recent pilot data have indicated that patients have a 40% increased risk of DKD for each 10 percentage points lower TIR [42].

Additional Treatment Strategies

In adults with T1D, the presence of microalbuminuria is a general indication for intervention with angiotensin converting enzyme inhibitors (ACEIs), angiotensin receptor blockers (ARBs), and/or statins. These recommendations are based on strong evidence that ACEIs decrease the progression of DKD and increase the likelihood of regression to normoalbuminuria. However, ACEIs have not been shown to prevent DKD [6]. Statin treatment may reduce rates of proteinuria and progression of chronic kidney disease in adults with T1D [6]. In adolescents with T1D, there is no definitive consensus on the use of ACEIs and/or statins when microalbuminuria is detected. Based on current guidelines, treatment with ACEIs is indicated only for those adolescents with persistent albuminuria, based on data from a few small studies [26, 27]. ACEIs are typically the first line treatment for persistent microalbuminuria, with ARBs being recommended for patients showing intolerance to ACEIs. A recent large clinical trial, the Adolescent Type 1 Diabetes cardiorenal Intervention Trial (AdDIT), assessed the effect of ACEIs for the prevention of DKD in adolescents that had ACR in the upper tertile of the normal range [43]. The trial did not show a clear effect of ACEIs in reducing ACR levels over a 2- to 4-year treatment period, although there was a trend for fewer new cases of microalbuminuria [43]. At a minimum, the trial provided reassuring data on the safety of ACEIs in this age group. ACEI side effects were mostly hypotension requiring dose reduction, whereas few patients developed cough [43]. At present clinicians should assess patients on an individual basis; in those with increasing ACR and/or other concomitant risk factors, ACEIs could be used given the good safety data [14]. If females are prescribed ACEIs/ARBs, it is important that they are counseled on the teratogenic risks associated with pregnancy [26, 27].

Guidelines recommend lifestyle interventions (diet and physical activity) as first steps to control dyslipidemia and hypertension [26, 27]. Initial treatment of elevated blood pressure includes dietary modification and increased exercise, but if targets are not reached within 3–6 months, pharmacologic interventions with antihypertensive drugs should be considered [26, 27]. ACEIs are the first line treatment when albuminuria is also detected. Similarly, if patients have dyslipidemia, a specific nutrition plan should be implemented first, followed by the introduction of a statin if LDL-cholesterol targets (<3.4 mmol/l or <130 mg/dL) are not reached. The AdDIT trial showed the beneficial effect of statins in reducing lipid levels and also provided important data on the safety of this class of medications in youth with T1D [43]. Raising awareness about the adverse effect of smoking and alcohol among youth with T1D and implementing strategies to prevent these habits are other key management strategies. Lifestyle interventions to prevent or reduce obesity rates are also recommended [26, 27].

Other Interventions

Several additional treatments have been investigated to better manage DKD and other vascular complications, mainly in adults with T1D, although data are often limited in younger patients. Sodium-glucose co-transporter 2 inhibitors (SGLT2i) have shown large benefits on cardiovascular and renal outcomes in adults with T1D. SGLT-2i may ultimately be beneficial in adolescents with T1D due to their high rates of hyperfiltration and evidence suggesting relatively low RAS activity with predominantly afferent dilation rather than efferent constriction in adolescents with T1D [44]. However, the risk for euglycemic ketoacidosis is a potential limiting adverse event for the use of these medications. There has also been interest in the potential role of uric acid in the pathogenesis of DKD and as a potential target for treatment. However, a recent trial did not show any clinically meaningful benefits of serum urate reduction with allopurinol on kidney outcomes in adults with T1D [45].

Conclusions

As the incidence of T1D continues to rise, particularly in children and adolescents, the burden of DKD will also increase and negatively influence the prognosis of young people with the disease. Therefore, early detection of risk factors and signs of DKD is of paramount importance to facilitate the early implementation of intervention strategies, which could reduce DKD development and/or progression. Further investigation to clarify etiological factors, both genetic and environmental, implicated in the pathogenesis of DKD, and the identification of new biomarkers, could better identify individuals at risk for developing DKD and guide more effective preventive and therapeutic strategies.

Abstract

Increasing epidemiologic evidence shows that obesity and metabolic syndrome (MS) are associated with increased risk of developing chronic kidney disease (CKD). Recent advances in the pathophysiology of obesity-related kidney disease indicate that hemodynamic factors, chronic inflammation, and abnormal lipid metabolism contribute to kidney injury. However, all components of MS, hypertension, atherogenic dyslipidemia, and type 2 diabetes mellitus (T2DM) may induce kidney damage. Children with severe obesity have increased prevalence of early kidney abnormalities, including hyperfiltration, albuminuria, and elevated early urinary biomarkers of kidney injury. Treatment of obesity through lifestyle modification is the mainstream of management of MS. If successful, it is typically associated with the reduction of all other MS cardiometabolic risk components. Pharmacological treatment with angiotensin converting enzyme inhibitors and bariatric surgery in case of severe obesity could provide long-term benefit by slowing the progression to CKD. Novel renoprotective agents, such as GLP-1 analogues and SGLT2 inhibitors need to be evaluated for clinical use in children and adolescents with MS.

Introduction

The obesity epidemic remains one of the most challenging health issues affecting children and adolescents at alarming rates. In 2016, the prevalence of obesity was 6% in girls and 8% in boys compared to less than 1% in both sexes in 1975. According to World Health Organization (WHO), in 2016 over 340 million children and adolescents were overweight; data from 2019 show 38 million overweight or obese children under the age of 5 years [1]. Cardiometabolic risk factors accompany overweight and obesity in children and adolescents with increased prevalence and severity in those at higher classification stages of obesity [2]. As body mass index (BMI) increases, the risk for cardiometabolic multimorbidity [3], and therefore the risk for metabolic syndrome (MS), defined as a constellation of three or more cardiometabolic risk factors in an overweight or obese individual, also increases. Since first described by Raven in the 1980s, the diagnosis of MS has been widely questioned in the literature. Definitions of MS in children have been published by many scientific organizations; however, a consensus to define MS has not been reached making it difficult to attain conclusive data on health outcomes in the pediatric population. Nevertheless, MS is an acquired, noncommunicable, possibly preventable disease. While screening, diagnosis and treatment of MS is mainly targeted in prevention of future cardiovascular disease [4]; it has been increasingly recognized that obesity and MS are significant risk factors for chronic kidney disease (CKD) [5], an association that seems to have its origins in childhood [6]. Thus, screening and management of MS in childhood may also alter long-term kidney outcomes.

Definitions of MS in Children

A uniform definition for MS in children and adolescents is lacking, and more than 40 definitions have been used in pediatric studies [7]. The most widely accepted definition of MS in children and adolescents has been proposed by the International Diabetes Foundation and includes central obesity as a necessary criterion with an addition of two or more cardiometabolic risk factors (Table 1) [8]. This definition focuses on visceral adiposity as the main drive between insulin resistance and cardiometabolic risk, such as hypertension and diabetes. Another widely used definition of MS in children developed by the National Heart, Lung, and Blood Institute does not include obesity as a necessary criterion [9]. None of the definitions focus on the severity of obesity which seems to be a major determinant of cardiometabolic clustering [2, 3].

Effect of Cardiometabolic Parameters on the Kidney

Mechanisms of Kidney Damage

Obesity-induced kidney damage has been extensively highlighted in the recent years. However, all components of MS, hypertension, atherogenic

Table 1 Definitions of metabolic syndrome in children and adolescents [8, 9]

	International Diabetes Federation 2007	Expert panel on integrated guidelines for cardiovascular health and risk reduction in children and adolescents 2011
Definition	WC ≥90th plus any 2 ≥ criteria	Any ≥3 of 5 criteria
Obesity	**6- <10 years:** WC ≥ 90th pc **10- < 16 years:** WC ≥ 90th pc or adult cut off if lower **>16 years:** WC ≥ 94 cm in Caucasian males or ≥ 80 cm in females or other ethnic specific values	BMI ≥ 85th pc or WC ≥ 90th pc
High triglycerides	**6- < 10 years:** NA **10- < 16 years:** ≥ 150 mg/dl >**16 years:** ≥ 150 mg/dl or treatment for high triglycerides	≥75 mg/dl if 0–9 years ≥90 mg/dl if ≥10 years
Low HDL	**6- < 10 years:** NA **10- < 16 years**: <40 mg/dl **>16 years:** <40 mg/dl in males <50 mg/dl in females or treatment for low HDL	≤ 40 mg/dl
Non-HDL	NA	≥ 120 mg/dl
High blood pressure	**6- < 10 years:** NA **10- < 16 years:** ≥130/85 mmHg **>16 years:** ≥130/85 mmHg or diagnosis of hypertension	≥ 90th age, sex, and height percentile
Glucose intolerance	**6- < 10 years:** NA **>10 years:** Fasting glucose ≥100 mg/dl or known type 2 diabetes mellitus	Fasting glucose ≥100 mg/dl

Abbreviations: BMI body mass index, WC waist circumference, HDL low density lipoprotein, NA not available

dyslipidemia, and type 2 diabetes mellitus (T2DM), may also individually induce kidney damage (Fig. 1). Metabolically healthy obese individuals (i.e., obesity in the absence of any cardiometabolic risk factors) present an at-risk population for future incident CKD, but their odds of having CKD is lower compared to metabolically unhealthy obese patients [6]. The number of clustering cardiometabolic risk factors is associated with higher odds for incidence or progression of CKD [10]. Of note, the duration of exposure to metabolic abnormalities that leads to irreversible kidney damage is not well defined by current evidence.

In obesity, hemodynamic changes and overproduction of adipokines and growth factors cause glomerulomegaly and ultimately focal-segmental glomerulosclerosis (FSGS) [11]. Hypertension causes kidney injury mainly through increase in intraglomerular pressure [12]. Atherogenic dyslipidemia, with low high-density lipoprotein (HDL) and high levels of triglycerides, induces endothelial damage in the blood vessels of the kidney and lipotoxic injury in glomerular, mesangial, and tubular cells [11]. Hyperglycemia-induced kidney damage involves several pathogenic pathways including increased formation of advanced glycation end-products, activation of protein kinase C isoforms both leading to oxidative stress and accumulation of inflammatory elements, as well as increased production of transforming growth factor β1 (TGF-β1) exerting profibrotic actions and inducing increased production of extracellular matrix (ECM) by mesangial cells [13]. Increased ECM accumulation causes thickening of the glomerular and tubular basement membranes, mesangial expansion, sclerosis, and tubulointerstitial fibrosis that are characteristic features of diabetic kidney damage [14]. Insulin resistance is associated with all components of MS and has a key role in the pathogenesis of kidney damage by inducing glomerular hyperfiltration and increased vascular permeability [14]. In addition, adipocytokine dysregulation and low-grade

inflammation, which mediate endothelial dysfunction and vascular damage, have been proposed as additional pathways involved in the modulation of kidney function in the presence of insulin resistance. Insulin resistance may also act at the level of the podocyte, regulating podocyte apoptosis, and thus, leading to glomerular basement membrane thickening, glomerulosclerosis, and albuminuria [13]. Finally, both in obesity and diabetes, increased ultrafiltration flow into Bowman's space heightens shear stress on the podocyte. This mechanical stress leads to an increase in glomerular basement membrane length and to podocyte hypertrophy.

Obesity-Induced Glomerulopathy

Obesity-induced glomerulopathy represents a distinct clinical entity characterized by proteinuria and progressive decline of renal function [11]. The primary histologic features might include relatively few FSGS lesions, glomerulomegaly, due to glomerular hyalinosis and fibrosis, as well as lipid accumulation in the glomeruli and adhesion to Bowman's capsule [11]. Glomerulomegaly is the defining feature presenting in 100% of cases. Perihilar glomerular sclerosis is common in obesity-induced glomerulopathy and might associate with greater ultrafiltration pressure [11]. As the glomeruli enlarge, the numerical density of podocytes decreases due to lower podocyte ability of adaptive hypertrophy eventually resulting in podocyte detachment and local denudation of the glomerular basement membrane and subsequently to FSGS development [11].

Early studies on adults with obesity-related kidney disease reported nephrotic-range proteinuria or decreased renal function with extensive histologic injury, glomerulosclerosis, and chronic tubulo-interstitial damage [15]. The outcome for these patients was poor, with up to 50% progressing to end-stage kidney disease (ESKD) within 10 years of diagnosis [15]. Of note, even patients with nephrotic range proteinuria rarely present with clinical features of nephrotic syndrome [11]. Isolated subnephrotic proteinuria is found in the majority of patients with obesity-induced glomerulopathy.

Importantly, pathological glomerular lesions may be found in extremely obese patients without clinical renal manifestations [16].

During the early phases of obesity, prior to loss of nephron function due to glomerular injury, obese individuals present with increased sodium reabsorption. This may be compensated for by renal vasodilation, increased glomerular filtration rate (GFR), and increased filtered amount of water and electrolytes as hypertension is compensated for by the pressure natriuresis. Increased intrarenal pressure caused by fat accumulation in the renal medulla compresses the loops of Henle and vasa recta, causes activation of the renin-angiotensin-aldosterone system (RAAS), and increases sodium reabsorption in both proximal and distal tubules [12]. Detection of the decreased amount of sodium, reaching the distal tubular cells, by the macula densa, leads to a rise in renin secretion, via tubuloglomerular feedback. Moreover, adipose cells may represent a major site where all components of the RAAS are formed. Renin, angiotensin II, angiotensinogen, and angiotensin II-receptors are found in abundance in adipose mass suggesting that a local tissue angiotensin system is present at the adipocyte level [12]. Overexpression of angiotensin II induces increase in proliferative factors such as TGF-β and plasminogen activator inhibitor. The tissue and the circulating RAAS components are in a state of constant interaction. RAAS activation might also contribute to hyperfiltration as angiotensin II and aldosterone have a greater vasoconstrictive effect on the efferent rather than the afferent arterioles. This results in imbalance between afferent and efferent renal vascular tones, and increasing transcapillary hydraulic pressure difference and therefore the GFR [11].

Adipokines secreted by the adipose tissue are shown to mediate kidney injury through chronic inflammation. Decreased levels of the adiponectin and high levels of leptin in obesity are associated with increased insulin resistance and inflammation with free fatty acid (FFA) accumulation. Adiponectin may prevent glomerular and interstitial damage, and low adiponectin in obese individuals has been associated with progression of kidney disease. Leptin actions through the hypothalamic neuronal systems include a decrease in food consumption and upregulation of thermogenesis and energy expenditure, via stimulation of sympathetic activity [12]. Leptin may also directly stimulate glomerular cell proliferation and mesangial cell hypertrophy [11].

Lipotoxicity due to increased fatty acid synthesis and defective free fatty acid (FFA) oxidation with increased accumulation of lipids and lipoproteins in glomerular and interstitial cells is another metabolic dysregulation of obesity that induces kidney damage [17]. Local overproduction of inflammatory cytokines and growth factors by free fatty acid accumulation and mitochondrial damage results in ongoing cellular injury [17].

Physical compression of both kidneys appears to generate from accumulation of adipose tissue around the organs emphasizing the crucial role of visceral obesity in the development of renal disease [12]. Deposition of ECM throughout the renal medulla is greatly expanded, and the tissue surrounding the ducts of Bellini at the vascular pole tends to prolapse. Increased numbers of interstitial cells and an increase in material rich in lipids and proteoglycans compress the renal parenchyma toward the pole of the kidney resulting in round-shaped, enlarged kidneys in obese subjects [18].

Epidemiological Evidence Linking Childhood MS to Kidney Outcomes

The main MS-related clinical outcomes that affect the kidney include intermediate endpoints (e.g., hyperfiltration, microalbuminuria, and kidney stones) as well as hard endpoints (e.g., ESKD). Still, the clinical course of kidney disease in childhood and adolescence is not extensively studied. The duration of MS might be a key factor for the risk of CKD [19].

Both renal hyperfiltration and hypofiltration have been reported in patients with MS [20, 21]. Although hyperfiltration may be seen at early stage and hypofiltration at late stage of kidney damage, the distinct components of MS may also have different impacts on the kidney. A study including 205,382 adults, aged 40–74 years, showed that hyperfiltration was associated with prehypertension and prediabetes, while hypofiltration was associated with dyslipidemia, abdominal obesity, overt hypertension, and overt diabetes [20].

Glomerular hyperfiltration, an early marker of obesity- or MS-related kidney disease may be evident before the appearance of histological changes and caused by the increased metabolic demands of obese individuals. Younger age, high-normal or elevated BP, and prediabetes may characterize obese individuals with hyperfiltration [20]. This may also be the case in children and adolescents [21–23]. A hyperfiltration state may be present, in part, due to intrarenal vasodilation induced by insulin resistance in a compensatory response to overcome the increased tubular reabsorption of sodium in obese individuals. In adolescents, evidence from the NHANES shows that hyperfiltration is associated with hypertriglyceridemia and insulin resistance even after accounting for BMI [24]. Higher GFR has been reported in the majority of population studies in obese children compared to those with normal weight [21–23, 25]. In a case-control study of 596 children and adolescents with overweight/obesity recruited from outpatient clinics in a single center in Italy, the prevalence of hyperfiltration and CKD stage 2 was higher compared to controls [21]. Reduced GFR has been reported in obese children in a population-based survey from Turkey. However, there was no statistical difference in the prevalence of CKD stages 2–5 when compared to children without CKD [26].

A meta-analysis on 57 studies in the general adult population showed a twofold higher risk for albuminuria and proteinuria in those with MS [27]. This association was independent of diabetes and more pronounced in men. The impact of MS was greater than each component separately with the number of clustering factors presenting a dose-response association for albuminuria risk. Obesity, the main MS component, has been consistently reported as an independent risk factor for microalbuminuria and/or proteinuria in several pediatric studies [21, 28–30]. In obese adolescents, increased urinary albumin-to-creatinine ratio (ACR) has been associated with fasting hyperinsulinemia, an impaired glucose tolerance test and hypercholesterolemia [31]. The prevalence of microalbuminuria in obese children has been reported from 0.3% in obese adolescents in the NHANES up to 14.7% in obese children from pediatric obesity clinics [23, 28–30, 32]. In the majority of studies, higher BMI was independently associated with both increased GFR and ACR. In one study, the main determinants of ACR were high serum insulin and triglyceride levels [32].

Adult-onset CKD is attributed mainly to diabetes and hypertension, and its progression could be accelerated in the presence of obesity. Childhood onset of these chronic conditions adds additional exposure years and could increase the risk for CKD in adulthood [25]. Of note, a preexisting state of a reduced number of nephrons as a result of perinatal, congenital, or unknown environmental and lifestyle factors or genetic predisposition cannot be excluded [25].

The effect of other MS components on the kidney in children without CKD has been reported in a few cohort and cross-sectional studies. Large population-based cohort studies from the Israeli ESKD registry suggest a role for cardiometabolic risk factors in adolescence on the incidence of ESKD in adulthood. In over two million asymptomatic healthy adolescents followed for a median period of 16.8 years, those with prehypertension had a 32% increased risk for subsequent ESKD, compared to adolescents with optimal BP [33]. In another study from the same registry including 1.2 million adolescents without a diagnosis of kidney disease, BMI at the age of 17 years was associated with increased incidence of future ESKD. Overweight and obesity were associated with 3 and 6.89 times (respectively) increased risk for all-cause-treated ESKD during 25 years of follow-up [5]. Similarly, in a case-control study from the Swedish National Population Register, being overweight at age 20 or obese at any later time point and without diabetes or hypertension was linked to an increased risk for CKD, suggesting causal pathways by elevated BMI [34].

MS and diabetes are considered among the major risk factors for uric acid nephrolithiasis [35]. Insulin resistance is inversely associated with renal ammonium synthesis and urinary pH, which increases the risk of developing uric acid nephrolithiasis, oxalate calcium stones, or a combination of both [35]. There are limited data in children and adolescents with MS. Increased serum uric acid levels have been reported in obese children with kidney stones [36].

MS-Related Kidney Outcomes in Special Populations

Children with Low Birth Weight and/or Prematurity

Low birth weight for gestational age and prematurity have been associated with reduced nephron numbers in humans [37]. Developmentally, programmed nephron deficit might contribute to the increased susceptibility to hypertension and renal disorders that are more prevalent among populations with a trend toward low birth weight, especially following exposure to subsequent renal stresses such as hypertension or diabetes. In children and adolescents born preterm and/or with low birth weight, subsequent overnutrition and obesity might act synergistically to augment the effects of developmental programming on the risk of kidney disease later in life. Based on the findings from a histopathological study in children with obesity-related nondiabetic proteinuric kidney disease, preterm patients were more likely to have reduced renal mass assessed by renal ultrasound, and obese preterm children had a twofold higher risk of progression to CKD stage 5 with a median renal survival of 15 years compared to 23 years in obese term children [38]. The synergistic effect of obesity on individuals with reduced nephron mass has also been shown in patients with unilateral renal agenesis or a severe reduction in renal mass as a result of medical or surgical intervention [39]. BMI at presentation was one of the factors significantly associated with the development of proteinuria and loss of renal function in these patients.

Preexisting-CKD and Kidney Transplantation

The detrimental effect of MS on progression of CKD has been well described in adults. The effect of MS on children with preexisting CKD is an emerging field. In the Chronic Kidney Disease in Childhood (CKiD) study, a multicenter, prospective cohort study in North America, among 472 children with estimated GFR 30–90 mL/min/1.73m^2 the prevalence of MS was 15.1% (40% among overweight patients and 60% among obese) [40]. MS was associated with twofold greater odds of an annualized eGFR decline of >10% [40]. The prevalence of MS is high in pediatric kidney transplant recipients ranging from 18% to 40% [41–43]. It has been reported that the likelihood of posttransplant MS is 16-fold higher compared to general pediatric population [44]. Steroid use is associated with the incidence or persistence of MS after kidney transplantation with prevalence up to 68% in those on steroids compared to 15–20% in steroid withdrawal groups [43, 45]. A faster decline of allograft function was observed in pediatric patients with MS at 1 and 1.5 years after kidney transplantation [45].

Most of the studies examining the effect of posttransplant cardiometabolic risk factors in children and adolescents on allograft function have mainly focused on hypertension and obesity, while the role of dyslipidemia and diabetes is less well studied. Hypertension was reported to associate with poorer graft survival in the long term [46], but the high BP detrimental effect on the graft is usually evident early after transplantation [47]. Obesity seems to have an adverse impact on graft survival [42, 48, 49], especially in cases with rapid weight gain after transplantation, although some studies showed neutral effect [50, 51]. Of note, all studies assessing the role of obesity postkidney transplant had a relatively short follow-up. Pretransplant excess weight has been associated with increased risk for posttransplant obesity [52], cardiometabolic risk factors, and worse graft survival [53]. Finally, large annual increase in BMI z scores has been associated with increased risk of death (adjusted hazard ratio 1.44, 95% confidence intervals 1.07–1.92) in a retrospective cohort of 1,182 pediatric dialysis and transplant patients [54].

Glomerular Disease

The prevalence of MS components is increased in children with glomerular diseases [55]. In a study from the CKiD cohort, including 586 children with an estimated GFR between 30 and 90 ml/min/1.73m^2, 15% were obese, 44% had dyslipidemia, 46% had hypertension, and 21% had abnormal glucose metabolism. Thirteen percent had three or more cardiometabolic risk factors and thus, by definition, having MS [56]. Glomerular disease was associated with 1.96 higher odds of cardiometabolic risk factor clustering. Data from a retrospective study in 446 pediatric patients with Henoch-Schoenlein Purpura Nephritis showed that obesity was associated with a 3.27 increased risk of progression to ESKD [57]. In adults with IgA nephropathy, obesity was associated with the presence of interstitial fibrosis and faster GFR decline [75, 76]. However, some studies question independent effect of obesity on progression of IgA nephropathy noting that the effect of obesity could be mediated by the higher cluster of cardiometabolic risk factors rather than obesity per se [58].

Renal Complications of Type 2 Diabetes Mellitus in Children and Adolescents

Two large studies of children and adolescents with T2DM conducted over last the two decades have evaluated the development of diabetic kidney disease (DKD). The SEARCH for Diabetes in Youth (SEARCH) study is an observational multicenter study focusing on physician-diagnosed diabetes (both type 1 and 2) in individuals less than 20 years of age [59]. It enrolled about 20,000 patients since year 2000, mostly patients with T1DM. Treatment Options for T2DM in Adolescents and Youth (TODAY) study assessed comparative efficacy of metformin alone, or in combination with rosiglitazone or lifestyle intervention [60]. A total of 699 participants were enrolled from 2004 to 2009. Both studies found high prevalence of microalbuminuria at initial assessment and progression during follow-up. In the TODAY study, the prevalence of microalbuminuria almost tripled (from 6.3% to 16.6%) over 4 years of follow-up [61]. The SEARCH study showed that in newly diagnosed patients with T2DM, more than 15% of participants had evidence of albuminuria progression during 7 years of follow-up [62]. Albuminuria progression was significantly more aggressive in patients with T2DM than in T1DM. Another SEARCH analysis showed that the odds of having DKD at 7 years after initial diagnosis of diabetes were 2.5 times higher in T2DM than in T1DM [63]. Nephropathy secondary to T1DM is discussed in detail in Chap. XXX.

Long-term kidney complications including incidence of ESKD in patients with childhood onset T2DM were examined in a cohort of Pima Indians [64]. The incidence of diabetic ESKD was 25 cases per 1000 person-years in youth onset diabetes less than 20 years of age and 5.4 cases per 1000 person-years in older onset [64]. ESKD was the second most common (after cardiovascular causes) cause of death in these patients. In another study, long-term kidney outcomes were compared in youth-onset T1DM and T2DM [65]. In this Canadian study, at 25 years follow-up, almost half of the patients with T2DM developed DKD while there were no kidney complications in patients with T1DM. Survival analysis showed that patients with T2DM had four times higher risk of developing any kidney complications as compared to patients with T1DM. The risk to develop ESRD in T2DM patients was 39 times higher when compared to healthy controls. The above studies strongly indicate that T2DM in children and adolescents is associated with a much higher risk of kidney complications than T1DM, and if they have preexisting CKD, this will greatly accelerate CKD progression.

The Effect of Nontraditional Cardiometabolic Factors on Kidney Outcomes

Nonalcoholic Fatty Liver Disease (NAFLD)

Nonalcoholic fatty liver disease (NAFLD) characterized by the accumulation of triglycerides within hepatocytes is the most common cause of pediatric liver disease. In children and adolescents, NAFLD has been consistently associated with obesity and insulin resistance and is a common comorbidity of MS. Children with MS have five times higher odds of having NAFLD than overweight and obese children without MS [66]. NAFLD is associated with all traditional cardiometabolic risk factors including diabetes, impaired fasting glucose, low HDL, high triglycerides, and hypertension [67].

NAFLD may share common pathogenic mechanisms with obesity-induced kidney damage, including lipotoxicity, oxidative stress, pro-inflammatory cytokines, and activation of RAAS. In adults, meta-analysis shows severity-dependent associations of NAFLD with incidence and progression of CKD [68]. Furthermore, NAFLD presents close associations with renal and cardiovascular outcomes in adult patients with pre-existing CKD [69]. In children and adolescents with NAFLD diagnosed by MRI imaging, obese children with NAFLD presented with significantly higher prevalence of estimated GFR <90 ml/min/1.73m^2 (17.5%) compared to obese children without NAFLD (6.7%) or healthy controls (0.77%). Similarly, albuminuria defined as urinary albumin greater than 30 mg/24 h was more frequent in obese children with NAFLD (9.3%) vs. obese children without NAFLD (4%) vs. controls (0%). In multivariable regression analysis, NAFLD was associated with 2.5 higher odds of decreased GFR and/or microalbuminuria independent of adiposity or other MS components [21].

Uric Acid

Elevated uric acid is a common finding in individuals with obesity, hypertension, and MS [70]. Hyperuricemia is found in CKD; however, epidemiological evidence of its role as a cause of CKD progression is inconclusive [70]. The potential mechanisms that uric acid may cause renal injury and hypertension include RAAS activation, inhibition of nitric oxide (NO) synthesis, vascular smooth muscle cell proliferation, and expression of cyclooxygenase-2 in the vascular wall [71]. The above mechanistic pathways promote interstitial fibrosis, afferent arteriopathy, glomerular hypertension, and glomerulosclerosis. In obesity, uric acid may reduce NO bioavailability in adipose cells promoting oxidative stress and insulin resistance [71]. In the National Health and Nutrition Examination Survey (NHANES) adolescent population, hypertension was more prevalent in those with uric acid levels >5.5 mg/dl [72]. Pediatric studies consistently show positive correlation of uric acid levels with BMI and systolic BP [32, 73]. In one randomized clinical trial, urate-lowering therapy in obese adolescents led to reduction of uric acid levels and decrease in BP levels [74]. Hyperuricemia is frequent in children with CKD and associated with increased BMI, hypertension, and albuminuria [75]. In the same study, high uric acid levels were associated with a 4.6 increased odds of having CKD stage 3–5 [75]. In a large study of obese children and adolescents in Italy (CARITALY study), uric acid levels >75th percentile for age and sex were associated with eGFR <90 ml/min/1.73 m^2, presence of NAFLD, or both [76]. Although the causative role of uric acid in the evolution of CKD in MS cannot be established by current evidence, high uric acid levels may be a marker of increased risk for CKD progression in children with MS.

Early Biomarkers of Kidney Injury

MS-related kidney injury is usually asymptomatic in children and adolescents. Recognition of early stages of kidney damage and detection of obese children at risk of adverse future renal outcomes are challenging. Common kidney biomarkers (e.g., serum creatinine or urinary ACR) might not reflect already present kidney involvement. Several candidate serum and urinary biomarkers have been investigated for their predictive value to diagnose kidney damage, including cystatin C, kidney injury molecule-1 (KIM-1), neutrophil gelatinase-associated lipocalin (NGAL), osteopontin, and metalloproteases with inconsistent results [77]. In adolescents with severe obesity without microalbuminuria and normal kidney function, urinary NGAL, IL-18, and KIM-1 were increased prior to bariatric surgery and remained increased 1 year after surgery, suggesting ongoing inflammation and possibly progressing tubulointerstitial fibrosis, despite weight loss and improvement of metabolic profile [78]. Sphingolipid urinary levels suggestive of lipotoxicity-induced glomerular injury were also reported elevated at 1 year after bariatric surgery in adolescents [79]. Still, more evidence is needed to establish the clinical significance of these biomarkers in "silent" kidney injury and their use in routine clinical practice.

Evaluation of Children with MS for Kidney Outcomes

Children and adolescents with MS should undergo evaluation for subclinical kidney damage or evident kidney disease. Frequency of assessment should depend on the number and severity of comorbidities. The presence of morbid obesity, diabetes, hypertension, history of low birth weight and/or prematurity, associated comorbidities (e.g., hyperuricemia), and preexisting kidney disease constitutes a high-risk profile for adverse future kidney outcomes. As described previously, the course of kidney disease in MS is usually asymptomatic for many years. Isolated microalbuminuria and hyperfiltration may be the first and only signs of kidney abnormalities before progression to CKD. Overt or nephrotic range proteinuria is rare in children with MS- and obesity-related kidney injury [6]. If significant proteinuria alone or in combination with hematuria or decreased GFR is present, other disease pathologies besides MS-induced causes of kidney disease should be ruled out (Fig. 2).

Physical examination includes anthropometry, weight, height, BMI calculation, and growth chart evaluation. Blood pressure measurement with an appropriate cuff may be challenging in obese adolescents, especially those with morbid obesity and conical shape arms. As cylindrical cuffs may overestimate BP, tronco-conical cuffs have been proposed for obese individuals with conical shared arms [80]. Acanthosis nigricans may be commonly present, while edema is a rare finding that could be associated with another kidney diagnoses. Dysmorphic features, especially in children with early onset of obesity would guide further evaluation for syndromic obesity such as Bardet-Biedl and Alstrom syndrome that are associated with obesity.

In addition to assessing fasting lipids, serum glucose levels, and HgA1C as part of MS, transaminases and uric acid levels may be included in the initial laboratory assessment to identify children and adolescents with comorbidities that could affect the kidney. Targeted screening for microalbuminuria might be included in the routine assessment of children with MS [6], especially in those with severe obesity and diabetes [23, 73], hypertension [81], or high triglycerides [32]. Assessment of serum creatinine and calculation of GFR would provide information for hyperfiltration state at early stages of kidney involvement, especially in those with diabetes and insulin resistance [23, 76]. If T2DM is among the presenting features of MS, albuminuria and kidney function should be monitored annually [82]. Evaluation with ABPM to detect abnormal BP phenotypes (e.g., white-coat or masked hypertension, nondipping profile, and nocturnal hypertension) should be considered in routine care, especially if sleep apnea, diabetes, or proteinuria are present [83]. Further evaluation including renal imaging and biopsy would be guided by the presence of proteinuria or abnormal kidney function. Finally, echocardiographic evaluation for left ventricular hypertrophy could be considered to complete the assessment of cardiovascular involvement with MS.

Treatment of MS-Induced Kidney Injury

The treatment of MS in children and adolescents, including those with CKD, should target each cardiometabolic component (Table 2). Lifestyle modification with diet, increased physical activity, and behavioral therapy remains the cornerstone of management. Weight loss ideally targets a BMI below the 85th percentile. Even a small initial decrease in BMI has been proven beneficial if maintained and could result in a decrease in cardiometabolic risk factors. A BMI-SDS reduction of 0.25 or greater significantly improved

hypertension, hypertriglyceridemia, and low HDL-cholesterol, whereas an increase of BMI-SDS greater than 0.5 doubled the effect in 1388 overweight children who underwent in 1 year lifestyle modification in a specialized obesity clinic [84].

Salt reduction according to the age-recommended daily dietary intake by WHO should be considered in children with MS [85]. Obese children usually consume high amounts of salt [86], and salt reduction may have beneficial effect on both weight and BP, especially in children with

CKD. A Cochrane review has shown that salt restriction results in decrease of BP and urinary protein excretion in patients with existing CKD [87]. Dietary Approaches to Stop Hypertension (DASH), which emphasize reduction of sodium intake along with increased fruits, vegetables, and low-fat milk products consumption, have beneficial effect on weight reduction and BP levels in adolescent cohort studies [88] and have been associated with a lower incidence of CKD in the general adult population [88]. On the other hand, high protein diets for weight loss should be avoided in children and adolescents with MS as this enhances hyperfiltration and is associated with rapid kidney decline in the general population [89].

In clinical practice, a significant proportion of children and adolescents may fail to comply with lifestyle medication or may regain weight after the end of lifestyle intervention program. Several reasons have been proposed including lack of family involvement, psychological issues, and even physiological hormonal adaptation during weight loss [90].

Pharmacological treatment for cardiometabolic risk factors should be considered in children and adolescents with MS, especially if kidney damage is present. Angiotensin Converting Enzyme (ACE) inhibitors or Angiotensin II receptor Blockers (ARB)s are considered the first-line treatment in the case of obesity-induced hypertension and may also have a beneficial reno-protective effect in youth with MS [81, 91]. Inhibition of RAAS may improve blood flow to muscles, decrease sympathetic nervous system activity, and improve insulin sensitivity. These agents may also have PPAR-γ effect on insulin sensitivity and are associated with a lower risk of diabetes [91]. Lipid treatment targeting low-density lipoprotein (LDL) cholesterol is also suggested for children and adolescents with MS [9]. Kidney Disease Improving Global Outcomes (KDIGO) guidelines suggest using statins in children with CKD aged $\geq$10 years with severely elevated LDL cholesterol, especially in those with multiple additional risk factors such as a family history of premature coronary disease, diabetes, hypertension, smoking, and ESKD [92]. Pharmacological treatment for high triglycerides levels, the main feature of dyslipidemia in children and adolescents with MS, is recommended in those with levels above 400 mg/dl [9, 82]. In adolescents with MS and T2DM, metformin is recommended in addition to lifestyle modification in those with an eGFR >30 ml/min/1.73m^2 [82]. New promising nephroprotective agents such as glucagon-like peptide 1 analogues and sodium-glucose cotransporter 2 inhibitors have shown significant reduction in cardiovascular and renal-specific outcomes in clinical trials of adults with T2DM [93]. These agents have not yet been evaluated in children and adolescents. Modifying hyperuricemia may have beneficial effect on BP levels in children with MS [74], but solid evidence on the protective effect against adverse kidney outcomes is lacking.

While treatment of hypertension, dyslipidemia, and abnormal glucose metabolism in children with MS is important, weight loss should be the main goal of treatment, including those with preexisting kidney abnormalities. It results in a reduction of proteinuria and microalbuminuria in obese individuals. Most of the data of the effect of conservative treatment on weight loss, diet, and physical activity interventions on kidney outcomes are reported in adults. Metaregression analysis in adults showed that 1 kg weight loss was independently associated with reduction by 110 mg in proteinuria and by 1.1 mg in microalbuminuria, respectively, but had no effect on creatinine clearance [94].

In youth, most of the data related to the effect of weight reduction on kidney outcome comes from studies in adolescents who underwent bariatric surgery. Bariatric surgery in adolescents can prevent or improve many health problems, including kidney abnormalities [95]. The results from the Teen Longitudinal Assessment of Bariatric Surgery (Teen-LABS) study showed improvement in albuminuria and kidney function. Prior to surgery, 14% of the cohort had microalbuminuria, 3% had macroalbuminuria, 3% had eGFR$<$60 ml/min/1.73 m^2 and 7.1% had eGFR$>$150 ml/min/1.73 m^2 [78]. At 3 years follow-up postsurgery, in participants with a preoperative eGFR $<$90 ml/min/1.73m^2, eGFR improved from a mean of 76–102 ml/min/1.73m^2 [96]. In those with elevated albuminuria at baseline (ACR $\geq$30 mg/g), the median ACR decreased from 74 to 17 mg/g. In another study, 5-year kidney outcomes were compared in adolescents with severe obesity and T2DM enrolled in the Teen-LABS (bariatric surgery) and TODAY (medical management) studies [97]. At baseline, elevated albuminuria was present in 21% and increased to 43% at 5 years in TODAY participants. In contrast, albuminuria decreased from 27% of Teen-LABS diabetic participants prior to surgery to 5% at 5 years follow-up. At 5 years, there were 27-fold higher odds of DKD in TODAY participants compared to Teen-LABS participants. A recent analysis of bariatric surgery in adults (LABS study) and adolescents (Teen-LABS) showed that adolescents experienced earlier remission of elevated albuminuria than adults [98]. These data indicate that bariatric surgery improves kidney outcomes in youth with severe obesity, including those with MS and T2DM, and may support the recommendation for bariatric surgery in adolescents who are near final-adult height and attained pubertal development if they have

$BMI \geq 40\ kg/m^2$ or $BMI \geq 35\ kg/m^2$ with significant obesity-related comorbidities who failed to respond to dietary or behavior modifications [95].

Abstract

While the majority of children with renal dysfunction have structural, immunological, or infectious disorders, some have metabolic defects arising from abnormalities in biochemical pathways of cell metabolism. This chapter focuses on metabolic diseases that compromise kidney function or cause renal structural abnormality and are not covered elsewhere in the textbook.

Introduction

While the majority of children with renal dysfunction have structural, immunological, or infectious diseases, a minority of patients have metabolic defects arising from abnormalities in biochemical pathways of cell metabolism. Progress in the treatment of many of these patients has considerably improved their survival and has often revealed renal symptoms that were not included in the original descriptions of the diseases. Pediatric nephrologists should remain vigilant to the possibility of a metabolic disease, especially when extra-renal symptoms are present. Kidney involvement in metabolic diseases is very heterogeneous. Renal tubules, in particular proximal tubules, have very high metabolic rates; hence, they are very sensitive to diseases that compromise cell energy production. Mutations in solute carriers that control metabolic pathways in other organs may cause tubulopathies. In other cases, metabolic dysfunctions cause nephrocalcinosis or urolithiasis. Glomerular lesions can result from abnormal depositions of metabolites, defects in the synthesis of structural components, or toxic damage to podocytes and endothelial cells. More rarely, metabolic diseases interfere in utero with normal embryogenesis, causing renal malformations. In many diseases, kidney involvement remains subclinical, even if substrate accumulation or enzyme defects can be demonstrated directly in the renal parenchyma. Sometimes, changes in urine color or odor are the only symptom. Finally, renal involvement can be secondary to damage to other organs, as in metabolic diseases that cause acute rhabdomyolysis or hemolysis.

Owing to the complexity of metabolic pathways, a large number of defects have been characterized at the molecular level. This has created the need to develop classifications that have been periodically updated. The latest revision includes 1015 well-characterized inborn errors of metabolism and 111 less well-characterized conditions [1]. Diseases are grouped along major metabolic pathways, since defects belonging to the same pathway are likely to share clinical features and may respond to similar treatments.

This chapter concentrates on diseases that are associated with renal and urological abnormalities and are not covered elsewhere in the textbook (i.e., cystinosis, Fabry disease, primary hyperoxaluria, galactosemia, tyrosinemia type I, hereditary fructose intolerance, glycogen storage disease type I, Fanconi–Bickel syndrome, methylmalonic acidemia, Wilson disease, amino acidurias, and mitochondrial cytopathies). Diseases are illustrated following the latest nosology for inborn errors of metabolism [1]. Given their elevated number, most diseases are only listed in Table 1, along with their most relevant renal and extra-renal symptoms; the OMIM reference ID is provided to facilitate retrieval of additional information. A selected number of diseases are also illustrated in more detail in the text below.

Congenital Diseases of Glycosylation

Congenital diseases of glycosylation (CDG) are a group of inherited multisystem diseases due to defective glycoprotein and glycolipid glycan assembly and attachment [2–4]. Protein glycosylation includes the addition of N-linked glycans, O-linked glycans, phosphorylated glycans, glycosaminoglycans, and glycosylphosphatidylinositol anchors to peptide backbones; glycolipids are obtained through the addition of sugars to lipids [5]. Different CDG subtypes have been described (see Table 1). The clinical presentation can be very heterogeneous, including cases presenting with cerebellar atrophy, epilepsy, movement diseases, multiple exostoses, progeria, developmental delay, or fatal multisystem diseases [4]. The most common CDG is a N-linked glycosylation disease termed PMM2-CDG (also known as CDG1a). Patients may present with dimorphisms, hypotonia, failure to thrive, diarrhea, abnormal fat pads, inverted nipples, abnormal eye movements, hepatomegaly, and cardiomyopathy. Laboratory investigations often show hypothyroidism and olivo-ponto-cerebellar atrophy [3, 4, 6]. The isoelectric focusing of serum transferrin is the first screening test to diagnose most CDGs, although it does not identify defects of O-linked glycosylation and other extremely rare forms. If abnormal, specific

Table 1 Metabolic diseases with renal involvement

Disease	OMIM	Gene	Inher.	Main features	Renal features	Tub.	Glom.	Int.	UL/ NC	CAKUT
Disorders of nitrogen-containing compounds										
Cystinosis (nephropathic)	219800	CTNS	AR	Failure to thrive, vomiting, rickets, often blond – fair hair, corneal cystine crystals, multisystem involvement	Fanconi syndrome, CDK	+	+	+		
Cystinosis (juvenile)	219900	CTNS	AR	Corneal crystals, retinopathy	Glomerulopathy, mild proximal tubular dysfunction	+	+			
Tyrosinaemia type 1	276700	FAH	AR	Hepatomegaly, acute/ chronic liver disease, hepatocellular carcinoma, rickets, neurological crises	Fanconi syndrome, CDK	+				
Lysinuric protein intolerance	222700	SLC7A7	AR	Failure to thrive, hepatosplenomegaly, vomiting, refusal of protein-rich foods, interstitial pneumopathy/ alveolar proteinosis, immune dysfunction, encephalopathy	Tubulopathy, CDK, hypertension, immune mediated glomerulonephritis, tubulo-interstitial nephritis.	+	+	+		
Cystinuria	220100	SLC3A1 SLC7A9	AR		Nephrolithiasis				+	
Classical homocystinuria	236200	CBS	AR	Marfan-like phenotype, lens dislocation, skeletal abnormalities, livedo reticularis, seizures, mental retardation, psychiatric disorders, cerebrovascular accident, large vessel thrombosis	Renal vein thrombosis

enzymatic and genetic tests should be performed [2–4].

The most common renal abnormality in CDGs is the presence of microcysts that give a hyperechogenic appearance to kidneys by ultrasonography and is usually observed in children with multisystemic involvement [6–8]. Cysts are located in the cortex, arise predominantly from tubules, and vary from case to case in number and size, even within the same family [7, 8]. Kidneys may be enlarged; occasionally, isolated cysts have been reported [6, 9]. In a large review of published PMM2-CDG cases, 56/933 patients were reported to have renal involvement [9]. Renal abnormalities were congenital in 41/56 cases [9]. Cystic kidney disease and mild proteinuria were the most common findings. Six patients presented with congenital nephrotic syndrome; postmortem biopsy was available in one case, showing diffuse mesangial sclerosis [9]. Proteinuria in PMM2-CDG contributes to the edema and ascites that these patients frequently develop [5]. Nephrotic syndrome has also been reported in B4GALT1-CDG, ALG1-CDG, and TMEM165-CDG [10–12]. Renal cysts have been reported in more rare defects, namely, in ALG6-CDG, ALG8-CDG, ALG9-CDG, and GANAB-CDG [9]. Patients with B3GALTL-CDG may present with hydronephrosis and other urological abnormalities; patients with ALG8-CDG and SLC35A1-CDG may develop isolated proteinuria; neurogenic bladder, obstructive uropathy, and tubulopathies have been reported in patients with COG7-CDG [3]. Transferrin isoelectric focusing should therefore be added to the list of investigations of patients with renal cysts, kidney malformations, isolated proteinuria, or nephrotic syndrome that present with multisystemic diseases or syndromic features.

Diseases of Purine and Pyrimidine Metabolism and Urate Transport

Children who develop uric acid urolithiasis, acute renal failure in the neonatal period, or crystal nephropathy may require investigation of their purine metabolism. Purines are involved in the synthesis of nucleotides and coenzymes, in signal transduction (e.g., cAMP) and in the generation of ATP. The metabolic end-product of these pathways, uric acid, and its immediate precursor, xanthine, are insoluble in urine. Therefore, overproduction predisposes to the development of urinary crystals and stone formation. Uric acid reabsorption in proximal tubules is age- and sex-dependent, with children reabsorbing less of the filtered urate load and consequently having lower plasma urate concentrations, but more uricosuria [13, 14]. As glomerular filtration rate declines, fractional excretion of urate increases [14]. Urolithiasis is the commonest renal manifestation of diseases of purine nucleotide biosynthesis, savage pathway, and breakdown. A rare disease of pyrimidine biosynthesis, UMPS deficiency, may also present with urolithiasis.

Diseases of the Purine Savage Pathway

This group of diseases includes adenine phosphoribosyl transferase (APRT) deficiency [15] and hypoxanthine-guanine phosphoribosyl transferase (HPRT) deficiency [16] (see chapter "Urolithiasis and Nephrocalcinosis"). Children may or may not have typical features of urinary calculi (pain, hematuria, infection). In some, the diagnosis is made following family studies or during investigation of crystalluria. Very rarely, these diseases present with oliguric acute renal failure, either due to bilateral obstructive stones or to crystal nephropathy, which can exceptionally occur during the neonatal period [16–18]. HPRT deficiency is an X-linked disease that encompasses a large spectrum of neurological and behavioral features, varying from severe early onset neurological symptoms, to asymptomatic hyperuricemic adults [19]. The most severe phenotype corresponds to Lesch-Nyhan syndrome that is characterized by cerebral palsy, choreoathetosis, pyramidal signs, self-mutilation, and undetectable HPRT activity [16, 19]. An intermediate form is represented by subjects with various degrees of neurological involvement, but no self-injurious behavior and residual HPRT activity [19]. HPRT-related hyperuricemia refers to subjects presenting only symptoms secondary to hyperuricemia that have enzymatic activities above 10% [19]. The pathogenesis of neurological and behavioral symptoms in these diseases remains unclear. Very rarely, heterozygous females can manifest severe neurological deterioration [20]. In both APRT and HGPRT deficiencies, urinary urate/creatinine ratio is normal. Plasma uric acid is normal in APRT deficiency, but is markedly elevated in HGPRT deficiency [13]. Both conditions are treated with a high fluid intake, restriction of dietary purines, and allopurinol, which inhibits xanthine oxidase. Rasburicase, a urate oxidase enzyme, has also been used to control hyperuricemia in Lesch-Nyhan nephropathy [17]. Neurological complications have been successfully improved using botulinum toxin injections, oral or intrathecal baclofen, or gabapentin (89).

Diseases of De Novo Purine Biosynthesis

Phosphoribosyl pyrophosphate synthetase I superactivity is a X-linked defect of purine nucleotide biosynthesis, secondary to mutations in the PRPS1 gene, resulting in increased enzyme activity [21]. Patients usually develop urolithiasis and have dysmorphic features in addition to neurological symptoms, including mental retardation, ataxia, developmental delay, and sensorineural deafness [21].

Diseases of Purine Breakdown

Defects of xanthine oxidase dehydrogenase (XOD) include type 1 xanthinuria, caused by isolated XOD deficiency, type 2 xanthinuria, due to deficiencies of both XOD and aldehyde oxidase (AOX), and molybdenum cofactor deficiency, resulting in combined deficiencies of XOD, AOX, and sulfite oxidase [21, 22]. Patients with type 1 and type 2 xanthinuria are clinically similar, but can be distinguished by the ability of type I patients to metabolize allopurinol, while those with type 2 xanthinuria cannot. Hereditary xanthinuria is characterized by very low urinary and plasma concentrations of uric acid and high urinary xanthine excretion, leading to urolithiasis. Many patients with xanthinuria are asymptomatic and are diagnosed after discovering hypouricemia. Rarely, patients develop acute renal failure, or myositis, due to excessive tissue deposition of xanthine [21, 22].

Diseases of De Novo Pyrimidine Synthesis

Among various diseases of pyrimidine metabolism, hereditary orotic aciduria type 1, caused by mutations in the uridine monophosphate synthase gene (UMPS), can present with urolithiasis. Patients often have anemia, which can be megaloblastic or microcytic, unresponsive to vitamin B12, folic acid, iron, or pyridoxine. They are diagnosed by detecting large amounts of orotic acid in their urine. Anemia and urinary orotic acid excretion are corrected by pyrimidine administration [21, 23].

Inherited Defects of Uric Acid Transport

Two rare diseases of uric acid transport cause hereditary renal hypouricemia that is characterized by impaired uric acid reabsorption in proximal tubules. Most patients are asymptomatic and are diagnosed by chance after noticing low serum uric acid levels. Patients may develop urolithiasis and/or exercise-induced acute renal failure in about 10% of cases. Renal hypouricemia type 1 is caused by homozygous or compound heterozygous mutations in the SLC22A12 gene [24, 25], whereas renal hypouricemia type 2 is caused by homozygous or compound heterozygous mutations in the SLC2A9 gene [24, 26]. Urinary alkalization with citrate compounds and hydration are effective in preventing stone formation. Exercise induced acute renal failure is usually self-limiting, without the need of dialysis. Allopurinol has been used as preventive therapy, but evidences of efficacy are lacking [24].

Lecithin-Cholesterol Acyl Transferase Deficiency

Lecithin-cholesterol acyl transferase (LCAT) is an enzyme required for the esterification of cholesterol with unsaturated fatty acid derived from lecithin. Patients with LCAT deficiency accumulate unesterified cholesterol and phosphatidylcholine in plasma and tissues [27]. Symptoms related to tissue accumulation develop during childhood and include grayish corneal opacities, hemolytic anemia and proteinuria, sometimes in the nephrotic range, leading to progressive kidney failure during adulthood [27, 28]. Tendon xanthomata and atherosclerosis have also been described [28]. Biochemically, LCAT deficiency is characterized by low total cholesterol concentrations, variable triglyceride levels, and abnormalities of lipoprotein structure and composition. Renal pathology shows mesangial hypercellularity and expansion, with foamy lipid depositions, vacuolization of the glomerular basement membrane, arteriolar narrowing secondary to intimal thickening and subendothelial lipid deposits [28]. In an Italian cohort of 18 patients, the median age at end-stage kidney disease was 46 years; the disease recurred in transplanted kidneys after approximately 10 years [29].

Lysinuric Protein Intolerance

Lysinuric protein intolerance (LPI) is an autosomal recessive defect of cationic amino acid (lysine, arginine, and ornithine) transport at the basolateral membrane of intestinal and renal tubular cells [30]. In addition, transport defects are also present in nonpolarized cells such as lymphocytes and macrophages [30]. The disease is caused by mutations in the SLC7A7 gene, which encodes for the y^+LAT1 protein; y^+LAT1 forms heterodimers with the protein 4F2hc, which is required for the expression of the transporter at the cell surface [31]. A founder effect explains high incidence of LPI in Finland (1/60,000 births) and to a lesser extent in Southern Italy and Northern Japan. Sporadic cases have been described worldwide. Most, but not all symptoms of LPI are related to derangements of the urea cycle. For long, the disease was considered to represent a benign condition if patients were treated with low-protein diet and citrulline. More careful analysis of LPI patients, however, has shown that LPI is a multisystemic disease and that a significant proportion of subjects develop complications, even under treatment [30, 32]. There is no overt genotype-phenotype correlation; disease severity varies significantly among patients carrying the same mutations. Symptoms range from nearly normal features to severe protein intolerance, failure to thrive, osteoporosis, hepatosplenomegaly, respiratory failure, chronic kidney disease, and immunological diseases, mainly pulmonary alveolar proteinosis, hemophagocytic lymphohistiocytosis, and immune-mediated glomerulonephritis [30, 32]. From the renal standpoint, the majority of patients have mild proteinuria with or without microscopic hematuria; some may progress to end-stage renal failure [32]. Proximal tubular damage, including overt Fanconi syndrome, may be present [32, 33]. In a review of 39 patients aged 1–62 years, 74% had proteinuria, 38% hematuria, 36% hypertension, 38% elevated plasma creatinine, and 4 patients required dialysis [34]. Renal biopsies show diverse pictures, including membranous glomerulonephritis, proliferative glomerulonephritis with immune complex deposits, tubulointerstitial changes, peritubular capillary inflammation, or amyloidosis [35–37]. The most severe cases usually die from pulmonary alveolar proteinosis [32]. High serum levels of inflammatory molecules are frequently observed in these patients, along with elevated ferritin and LDH levels [30, 38].

Typically, patients prefer low-protein foods, but this may lead to nutritional deficiencies [39]. The aim of treatment is to prevent hyperammonemia, while providing sufficient amounts of proteins to allow normal growth. Oral supplementation with L-citrulline primes the urea cycle, preventing postprandial hyperammonemia, and increases protein tolerance [31, 40]. Immune diseases, including glomerular lesions, respond to immunosuppressive treatments, but no systematic studies are available.

Abstract

Different inherited metabolic diseases in the cobalamin pathway show a heterogenous kidney involvement. Isolated methylmalonic acidaemias are caused by defects in the genes *MMUT*, *MMAA*, or *MMAB* and are characterized by the accumulation of methylmalonic acid in blood and urine. Possibly due to toxic metabolite effects and a mitochondrial energy deficiency, these disorders result in tubulointerstitial nephritis and progressive kidney failure. Defects elsewhere in the cobalamin pathway, namely, in the genes *MMACHC* and *MTR*, can cause hemolytic uremic syndrome. Raised homocysteine and scarce methionine levels are held accountable to precipitate the kidney pathology. Furthermore, Imerslund-Grasbeck syndrome, caused by proximal cobalamin pathway defects in *CUBN* and *AMN*, is leading to a malabsorption of cobalamin from the gut due to a deficiency of the cubam receptor failing to take up the complex of cobalamin and the intrinsic factor. From a kidney standpoint, these patients suffer from a persistent nonprogressive proteinuria.

Introduction

Methylmalonic acidaemia (MMA) is a group of inherited metabolic diseases, caused by a deficiency of the methylmalonyl-CoA mutase (MMUT) enzyme, either by a direct defect in the *MMUT* gene (OMIM #609058) or a defective synthesis and targeting of the adenosylcobalamin cofactor, which is facilitated by the MMAA and MMAB proteins (*MMAA* gene, OMIM #607481; *MMAB* gene, OMIM #607568) (Fig. 1) [15]. Under physiological conditions the MMUT enzyme converts methylmalonyl-CoA to succinyl-CoA, while in case of the above listed gene defects, a dysfunctional MMUT protein leads to the accumulation of several metabolites, including methylmalonic acid, 2-methylcitric acid, and 3-hydroxypropionate in body fluids, allowing the biochemical diagnosis of the disease based on urine organic acid analysis. Historically, *MMUT* defects are classified as mut^0 in case of an absent response to hydroxocobalamin in the in vitro propionate incorporation assay or as mut^- if propionate incorporation could be enhanced by supplementation of hydroxocobalamin in the cell culture medium [13].

Clinically, MMA presents heterogeneously. Early-onset patients present in the neonatal period with severe metabolic acidosis, leading to lethargy, vomiting, poor feeding, and a sepsis-like clinical picture. In addition to the acidaemia, ketones can be present in urine, and patients might have hyperammonemia, due to secondary inhibition of the urea cycle by toxic metabolites. If untreated, symptoms worsen and progress to coma and eventually death. Milder forms of MMA also exist. Those patients present later in life with developmental delay, hypotonia, seizures, anemia, and failure to thrive. In surviving patients, long-term complications comprise chronic kidney failure and neurological impairment, including movement disorder due to metabolic stroke-like episodes. Patients are generally at risk of metabolic decompensations, which can be triggered by catabolic metabolism due to an infection, diarrhea, vomiting, or prolonged fasting. *MMUT* defects that have significant cobalamin responsiveness in vitro and in vivo (designated mut^-, as compared to mut^0) and MMAA deficiencies seem to be associated with a milder course of the disease [21].

Clinical Symptoms and Biochemical Markers of Kidney Disease in MMA

Renal disease is one of the most devastating long-term complications observed in MMA patients leading to end-stage kidney disease in up to 15% of patients [8]. A European study found that 24% of pediatric and 29% of adult patients have a creatinine clearance of less than 60 mL/min/1.73 m^2 (according to the Schwartz formula) [27]. Another study observed chronic kidney disease (CKD) in almost 50% of patients with a median age of onset of 6.5 years [21]. Of note, mut^0 patients are affected earlier in life (one of the earliest cases of kidney impairment is reported at 18 months of life [41]) compared to *MMAB* patients; in patients with a mut^- or *MMAA* subtype, renal impairment is even milder [17, 21, 22, 27]. These differences were mostly observed in cross-sectional studies, while it is assumed that MMA patients of all subtypes are at risk of developing kidney impairment in the long term [38]. Some studies point toward an association of the severity of CKD with the level of urinary excretion of methylmalonic acid [21], while others do not find quantitative methylmalonic acid excretion to be a predictive factor of glomerular filtration rate (GFR) [1].

Evaluation of kidney function based on creatinine clearance can be unreliable as MMA patients

Fig. 1 Overview of the cobalamin pathway. After nutritional uptake, cobalamin (Cbl) binds to the intrinsic factor (CBLIF) in the duodenum. Uptake in the terminal ileum is facilitated by the two proteins amnionless (AMN) and cubulin (CUBN), which form the cubam receptor at the apical brush border. Following endocytosis, CBLIF is degraded, and free cobalamin is exported into the bloodstream, where it is bound to haptocorrin (TCN1) and transcobalamin (TCN2). The latter form can be taken up by most body cells after recognition by the transcobalamin receptor (CD320). In the lysosome TCN2 is cleaved off, and the cobalamin molecule is released into the cytosol by the two integral membrane proteins ABCD4 and LMBD1. In the cytosol, MMACHC cleaves off the upper-axial ligand of cobalamin (R group). From there, MMADHC targets cobalamin toward two destinations: (i) cobalamin is used as a cofactor by the cytosolic enzyme methionine synthase (MS) in its methylated form (methylcobalamin, Met-Cbl; MSR, methionine synthase reductase); (ii) in the mitochondrion, adenosylcobalamin (Ado-Cbl) is formed and targeted to methylmalonyl-CoA mutase (MMUT) by MMAB and MMAA. Proteins whose defects are discussed in this chapter are in bold print

have decreased muscle mass [20]. Serum creatinine may be falsely decreased in patients with low muscle mass, leading to an overestimation of kidney function and rendering creatinine poorly predictive of kidney impairment early in disease progression. Estimation of GFR is more accurate using cystatin C, as this biomarker is independent of muscle mass [28]. Cystatin C has been shown, among other factors (height, serum methylmalonic acid concentration), to correlate with kidney growth [28]. Lipocalin-2 has also been used as an alternative biomarker [31, 32], while fibroblast growth factor 21 (FGF21), another recently developed disease biomarker, does not seem to correlate with kidney function [35].

Pathophysiology of Kidney Disease in MMA

Two main pathological renal conditions have been observed in MMA patients: (1) chronic tubulointerstitial nephritis presenting with decreased reabsorption of phosphate, reduced urinary concentrating ability, impaired acid balance, and characterized by interstitial infiltration of inflammatory cells and fibrosis [10, 16, 37] and (2) type 4 renal tubular acidosis with hyperkalemic hyperchloremic metabolic acidosis, hypoaldosteronism, and impaired urinary acidification [37, 49]. Kidney disease in a hypomorphic mouse model of MMA has been shown to cause reduction in urine output, urinary electrolyte losses (sodium, chloride, potassium, calcium, magnesium), and elevated plasma urea [14]. In general, reduced cytochrome C enzyme activity and multiple deficiencies of oxidative phosphorylation as well as structural mitochondrial changes have been noted in MMA models [26, 51]. The exact pathomechanisms remain unsolved, but several detailed studies highlight the effects of toxic metabolites and energy deficiency in the context of mitochondrial impairment as direct consequences of a dysfunctional MMUT enzyme.

Mmut knockout mice are normally nonviable [43]. Manoli *et al.* devised a viable mouse model by expressing a stable *Mmut* transgene under the control of an albumin promoter on a null background to study kidney function in a mammalian model of MMA [32]. The authors found decreased GFR and chronic tubulointerstitial nephritis as observed in patients. More strikingly, they noticed proximal tubule mitochondria with an electron-dense matrix and abnormal cristae morphology associated with abnormal tubular function; the glomeruli and podocyte foot processes appeared normal. Oral treatment of mice with CoQ_{10} or vitamin E led to mitigation of GFR losses and normalization of the plasma biomarker lipocalin-2, suggesting a role of oxidative stress in the pathomechanisms of MMA.

Ruppert *et al.* established an *in vitro* model of tubular epithelial cells derived from patient urine, where they discovered disturbed glycolysis, mitochondrial respiratory chain function, and tricarboxylic acid cycle, together with raised levels of reactive oxygen species [44]. Further, the authors found an increased number of autophagosomes and endoplasmic reticulum stress.

More recently, Luciani *et al.* used patient-derived kidney tubular cells, mouse proximal tubule cells from floxed *Mmut* kidneys, and *mmut*-deficient zebrafish to provide extensive data illustrating that MMUT deficiency induces accumulation of dysfunctional mitochondria which trigger epithelial stress [31]. The authors identified PINK1/Parkin-mediated mitophagy as a key mechanism, which is dysfunctional in MMA, leading to an accumulation of ROS, impaired ATP production, and collapsed mitochondrial membrane potential.

Taken together, current knowledge suggests that effects on mitochondria, rather than elevations in methylmalonic acid per se, are responsible for GFR decrease associated with proximal tubular mitochondrial dysfunction [31, 32]. Interestingly, recent reports have also observed that patients with propionic acidaemia (PA) may develop kidney dysfunction [29]. PA is caused by a defect of propionyl-CoA carboxylase, the enzymatic step just proximal to MMUT. PA patients present with a very similar, although often more severe, phenotype but with milder and more delayed kidney dysfunction [4]. Thus, although recent findings have challenged previous hypothesis suggesting that methylmalonic acid acts as a toxic agent for the kidney [25, 49], the significantly milder kidney phenotype observed in PA suggests that there may still be a pathophysiological role of methylmalonic acid in the development of MMA-associated kidney disease.

Renal-Related Complications in MMA

Some complications observed in MMA patients are secondary to kidney impairment or are at least partly influenced by a dysfunction of the kidney. These symptoms include anemia, arterial hypertension, renal osteodystrophy, and hyperparathyroidism [37]. MMA patients are at risk of low bone density due to chronic acidosis, inadequate nutritional intake of calcium and phosphate (as a consequence of low natural protein diet), and low vitamin D levels (secondary to impaired renal synthesis), leading to hyperparathyroidism and calcium mobilization from the bones [21]. Further, cytopenia of all blood lineages has been described in MMA [3]. Neutropenia and thrombocytopenia can occur chronically or during an acute metabolic decompensation, while anemia is usually a chronic problem possibly due to insufficient production of erythropoietin by the failing kidney.

Treatment Options

Clinical guidelines for MMA provide assistance for the management of MMA patients [4]. The mainstay of MMA therapy consists of a specific diet low in natural protein to limit the intake of precursor amino acids (valine, threonine, isoleucine, methionine) which funnel into the MMUT pathway. This regimen can be supplemented with precursor-free amino acid mixtures. Further, levocarnitine is given to conjugate and excrete toxic intermediary metabolites, such as propionyl-CoA and methylmalonyl-CoA, and to replenish lowered free carnitine levels. All patients should be evaluated clinically for cobalamin responsiveness by intramuscular administration of hydroxocobalamin [15].

Due to the lack of high-grade evidence, guidance on the treatment of kidney dysfunction in MMA is mostly limited to standard treatment strategies. Hemodialysis and peritoneal dialysis have been successfully applied in patients with end-stage renal disease [12, 21]. Also, hemodialysis is often used as an emergency therapy to treat hyperammonemia or severe metabolic acidosis during metabolic decompensation and together with other improvements in intensive care medicine is probably one of the reasons explaining decreased morbidity of MMA disease over the last decades [18].

Combined liver and kidney transplantation can effectively treat kidney failure in MMA patients, with good renal outcome up to 10 years post-transplant [9, 11, 36, 48, 50]. Isolated kidney transplant has been performed as well and found to improve kidney function for a similar amount of years in some reports [5, 7, 30], but in other cases, reoccurrence of renal dysfunction and kidney failure has been reported after transplantation. Isolated liver transplantation appears to preserve kidney function only in some cases, and progressive kidney failure has been described in several cases post-liver transplant [9, 24, 40, 46]. There are no reports of improvement of an already dysfunctional kidney after liver transplantation [45]. Overall, organ transplantation in MMA remains controversial, as detailed effects on the manifold of outcome parameters have not been studied in the long term, and especially neurological complications do not seem to be cured/avoided by this mode of therapy [34, 39].

There is still a considerable unmet need for effective therapies for MMA patients. Future developments might include treatment modalities based on genome editing or the usage of messenger RNA. A specific lipid nanoparticle formulation in combination with an mRNA expression cassette has been successfully used to treat *Mmut*-deficient mice [2]. For AAV-based approaches, novel virus capsids are currently being evaluated.

Other Defects in the Cobalamin Metabolism

In addition to the above-described forms of isolated methylmalonic acidaemia, further genetic defects in the cobalamin pathways exist [23].

Among others, defects in the *MMACHC* (OMIM #609831) gene cause methylmalonic aciduria and homocystinuria. Defects in the *MTR* (OMIM #156570) and *MTRR* (OMIM #602568) genes lead to a deficiency of the methionine synthase (MS) enzyme and the biochemical phenotype of isolated homocystinuria. In both, MMACHC and MS deficiency, hemolytic uremic syndrome has been observed as a renal complication. The pathomechanisms are different to the ones discussed above for isolated MMA and include (i) a toxic effect of homocysteine and (ii) the lack of the downstream metabolite methionine. Homocysteine might damage the glomerular endothelium, leading to a pro-thrombotic milieu secondary to induced tissue plasminogen activator, activated inflammatory pathways, and accumulation of intracellular radicals [19, 37, 42, 47]. Methionine deficiency might be partly responsible for the type of vessels which are affected [33].

Lastly, gene defects further proximal in the pathway (*CUBN*, OMIM #602997; *AMN*, OMIM #605799) lead to a defective absorption of the cobalamin-intrinsic factor complex and to the clinical picture of Imerslund-Grasbeck syndrome. These patients present with decreased serum cobalamin, low-molecular-weight proteinuria, and mild clinical symptoms (failure to thrive, loss of appetite, fatigue, lethargy) [6].

Abstract

Mitochondria are small dynamic intracellular organelles with critical roles in energy generation and other aspects of cellular homeostasis. Mitochondrial disorders, which are estimated to have a population prevalence of at least 1 in 4300, are monogenic diseases associated with dysfunction of the oxidative phosphorylation system, mitochondrial ultrastructure and dynamics, production of cofactors and vitamins, or other metabolic processes within the mitochondrion. Renal manifestations are a relatively frequent complication of mitochondrial disease and include Fanconi-type tubulopathy, chronic tubulointerstitial nephritis, steroid-resistant nephrotic syndrome, and cystic glomerular disease. Isolated kidney disease is a rare presentation of mitochondrial disease, although it does occur, particularly in some types of coenzyme Q_{10} (CoQ_{10}) deficiency. More frequently, renal involvement is part of a complex multisystemic disease. The genetics of mitochondrial disease is complex and includes mutations of the intrinsic mitochondrial DNA (mtDNA) as well as more than 300 nuclear-encoded Mendelian disorders affecting mitochondrial function. The most frequent causes of mitochondrial nephropathy are point mutations and large-scale rearrangements of the mtDNA and autosomal recessive disorders of CoQ_{10} biosynthesis. Increasingly, exome and genome sequencing of large cohorts is leading to the identification of novel genetic causes of mitochondrial kidney disease, including disorders of mtDNA maintenance, mitochondrial translation, mitochondrial dynamics, and biosynthesis of membrane lipids and iron-sulfur clusters. Diagnosis is challenging, as there may be few clues from renal or muscle biopsy and biochemical testing, and the approach to diagnosis increasingly involves genome-wide next generation sequencing.

Introduction

Mitochondria are small dynamic intracellular organelles that play a central role in cellular homeostasis. Their principal function is the generation of ATP through oxidative phosphorylation (OXPHOS). The OXPHOS system comprises five enzymatic complexes and two electron carriers, cytochrome *c* and coenzyme Q_{10} (CoQ_{10}). Mitochondria host several other metabolic pathways and control intracellular calcium homeostasis and the intrinsic apoptotic pathway [1, 2]. Mitochondria possess their own genome (the mitochondrial DNA, mtDNA) that is a 16,569 base pairs long circular molecule, lacks introns, and has its own genetic code (different from the universal code) for protein synthesis. However, the vast majority of genes needed for mitochondrial function are encoded in the nucleus. MtDNA is present in multiple copies per mitochondrion (and in hundreds of copies in each cell), and its transmission does not follow the laws of Mendel. Firstly, mtDNA is inherited only from the mother (**Maternal Inheritance**). Both males and females may be affected by a mtDNA-related disorder, but only females will transmit it to their offspring. Secondly, wild type and mutant mtDNA molecules coexist in different proportions within cells of the same tissue, or within different tissues of the same individual (**Heteroplasmy**). Thirdly, mutations must affect a critical proportion of the total mtDNA in order to cause a biochemical or clinical phenotype (**Threshold Effect**). Fourthly, mtDNA molecules segregate randomly in daughter cells at cell division (**Random Drift**). Tissues with high cell turnover, such as the bone marrow, are more likely to be relatively spared because cells with higher mutation loads are cleared during proliferation. Conversely, postmitotic cells, such as neurons or renal cells, tend to accumulate mutations and are more likely to develop mitochondrial dysfunction [3].

MtDNA encodes 37 genes, including 13 OXPHOS subunits, and the 22 transfer RNAs (tRNAs) and 2 ribosomal RNAs (rRNAs) required for mitochondrial protein synthesis. OXPHOS complexes contain more than 80 subunits in total. Hundreds of other proteins are required for mtDNA maintenance, replication, transcription, and for mitochondrial protein synthesis and cofactor biosynthesis, all of which are encoded by nuclear genes, synthesized in the cytosol and then imported into mitochondria. Hence, OXPHOS biogenesis requires the coordinated action of two distinct genomes, and its dysfunction may result from mutations in either mitochondrial or nuclear genes (Fig. 1) [4].

OXPHOS dysfunction causes a wide spectrum of clinical phenotypes that may present at any age and may affect virtually any tissue, although those that rely the most on aerobic metabolism (nervous system, skeletal and cardiac muscle) are usually most severely affected. In recent years, it has become evident that renal involvement is not at all rare in these disorders.

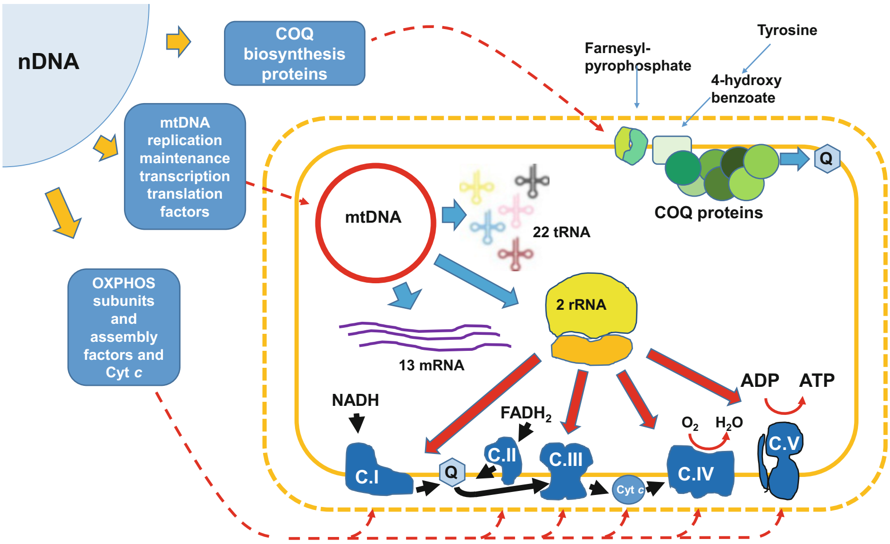

Fig. 1 Relationships between the nuclear (nDNA) and mitochondrial (mtDNA) genomes in the biogenesis of the mitochondrial oxidative phosphorylation (OXPHOS) system. mtDNA provides 13 mRNAs encoding OXPHOS structural subunits [7 of complex I (C.I), 1 of C.III, 3 of C.IV, and 2 of C.V) and the ribosomal RNA (rRNA) and transfer RNA (tRNA) molecules required for mitochondrial protein synthesis. nDNA provides more than 70 other subunits of OXPHOS complexes, as well as cytochrome *c* (Cyt *c*), assembly factors, and all other factors required for mtDNA replication, maintenance, transcription, and translation. nDNA also encodes the proteins required for Coenzyme Q_{10} (COQ, Q) biosynthesis. The black arrows depict the flow of electrons between the different complexes and electron carriers

Mitochondrial DNA Defects Associated with Kidney Disorders

Primary mtDNA defects comprise point mutations (the most frequent is the m.3243A>G in *MT-TL1*-encoding tRNA$^{Leu(UUR)}$, present in 1 in 400 of the population) and gross rearrangements (essentially deletions) which typically span from 2 to 8 kb in size [5]. Point mutations may affect the 13 structural subunits, and tRNA or rRNA genes. Mutations of tRNAs and rRNAs impair mitochondrial protein synthesis as a whole. This is true also for large deletions, since they always include at least one tRNA gene (Table 1).

Because some residual OXPHOS activity is essential for development, pathogenic mtDNA variants are usually heteroplasmic, i.e., a certain proportion of wild type mtDNA molecules are still present. Conversely, polymorphisms are usually homoplasmic (i.e., they affect all mtDNA molecules in an individual), although a few bona fide homoplasmic mtDNA-pathogenic variants causing renal dysfunction have been reported (and confirmed by subsequent reports or functional studies) such as the m.616T>C in *MT-TF* encoding tRNA^{Phe} (Table 1) [4, 6].

MtDNA mutations have been associated with proximal or distal tubular dysfunction, and with glomerulopathies; more rare phenotypes are tubulointerstitial nephritis (TIN) and cystic glomerular disease (Table 1) [7]. Renal involvement can be an isolated manifestation or, more frequently, a part of a complex syndrome, affecting other tissues. The most common mtDNA-related syndromes associated with renal involvement are Kearns-Sayre (KSS) and Pearson syndromes, mitochondrial encephalomyopathy, lactic acidosis, and stroke-like episodes (MELAS), and maternally inherited diabetes and deafness (MIDD), but there are also patients whose symptoms do not fit into any of these syndromic diagnoses. In some cases, renal manifestations are the presenting symptom, and extrarenal involvement may become evident only after months or years (leading to significant diagnostic delay), and in other cases the renal disease remains the only manifestation [8, 9]. The complexity of inheritance and transmission of mtDNA explains only part of the phenotypic variability. Genotype phenotype correlations are still not clearly understood. Our knowledge of the pathophysiology of these conditions is still limited, and we lack animal models for these diseases, although the recent discovery of enzymes capable of mtDNA base editing may finally allow the generation of mouse models harbouring specific mtDNA mutations [10].

The proximal and distal tubules have high energetic demands and are rich in mitochondria. Tubular involvement is observed frequently in mitochondrial disorders and is linked to ATP deficiency. Proximal tubular dysfunction may range in severity from complete Fanconi syndrome with low-molecular-weight proteinuria, to partial defects, such as isolated renal tubular acidosis, glycosuria, aminoaciduria, a Bartter-like phenotype, or even isolated hypermagnesuria. In the majority of cases, these manifestations are seen in the context of a multisystemic disorder (such as KSS). Most of these patients harbored deletions of mtDNA, more rarely point mutations such as the m.8344A>G in *MT-TK* encoding tRNA^{Lys} which has been associated with aminoaciduria (Table 1) [11].

Several patients have been reported in the literature with dysfunction of the distal convoluted tubule, presenting with specific electrolyte alterations, most frequently hypomagnesaemia and hypokalemia. Again, patients displayed in most cases a multisystemic phenotype and harbored mtDNA deletions.

The glomerulus relies less on OXPHOS since anaerobic glycolysis maintains glomerular filtration independent of mitochondrial metabolism [12]. Nevertheless, glomerular involvement is often observed in MELAS and MIDD, associated with the m.3243A>G mutation [13]. Clinical manifestations may range from proteinuria, often without haematuria, to overt nephrotic syndrome, with progression to renal failure. The histological picture is usually characterized by focal and segmental glomerulosclerosis. These patients are often misdiagnosed with Alport syndrome due to coexistence of sensorineural hearing loss (SNHL). However, absence of haematuria and typical histopathological features characterizing

Table 1 Mitochondrial kidney disease: examples of molecular mechanisms

Molecular defect	Gene(s)	Inheritance	Renal manifestations	Other clinical phenotypes
mtDNA-encoded				
Large-scale rearrangements of mtDNA	Multiple	Sporadic	Fanconi-type tubulopathy, tubulointerstitial nephritis	Pearson and Kearns-Sayre syndromes, PEO

Other disease mechanisms	*C1QBP*	AR	Congenital nephrosis	HCM, multisystem disease

Key: 3MGA, 3-methylglutaconic aciduria; AR, autosomal recessive; CAKUT, congenital abnormalities of the kidney and urinary tract; FSGS =; GRACILE, growth retardation, amino aciduria, cholestasis, iron overload, lactic acidosis, and early death; HCM, hypertrophic cardiomyopathy; HUPRA, hyperuricaemia, pulmonary hypertension, renal failure, and alkalosis; IUGR, intrauterine growth restriction; MEGDEL, 3-methylglutaconic aciduria, deafness, and Leigh-like encephalomyopathy; MELAS, mitochondrial encephalomyopathy, lactic acidosis, and stroke-like episodes; MERRF, myoclonic epilepsy with ragged red fibres; MIDD, maternally inherited diabetes-deafness; and PEO, progressive external ophthalmoplegia

Alport syndrome facilitates ascertainment of the correct diagnosis. Other mtDNA point mutations, and occasionally deletions, may present with glomerular involvement [5]. The pathogenesis of glomerular dysfunction is still not clear. In general, defects in OXPHOS produce two major effects: a decrease in ATP production and an increase in generation of reactive oxygen species, each of which has been implicated in the pathogenesis of the renal manifestations of mitochondrial disease. In addition, defects in electron carriers such as CoQ_{10} and cytochrome *c* also affect apoptosis as they have important roles in this process by modulating the mitochondrial permeability transition pore, which acts as a gating channel for apoptosis [1, 9].

Chronic TIN is a histopathological rather than clinical diagnosis, and it is characterized by the presence of tubulointerstitial inflammatory cell infiltrates and interstitial edema. Clinically, patients present with nonspecific symptoms such as renal failure and low molecular weight proteinuria. TIN has been associated with mtDNA deletions, and with several point mutations, especially in *MT-TF*. Finally, glomerulocystic disease has been associated with a mutation in the *MT-ND5* gene (Table 1) [5].

Nuclear-Encoded Mitochondrial Kidney Disorders

Coenzyme Q_{10} Deficiencies and Related Nephropathies

Primary CoQ_{10} deficiencies are unique among mitochondrial disorders, as they are amenable to treatment with exogenous supplementation of CoQ_{10}. They therefore deserve special emphasis since early diagnosis and CoQ_{10} supplementation are essential to prevent sustained organ damage. In common with all mitochondrial diseases, this group of autosomal recessive disorders is clinically and genetically heterogeneous. Kidney involvement may be isolated or occur as part of a multisystemic disease [9]. In many affected individuals, progressive kidney disease is characterized by proteinuria or steroid-resistant nephrotic syndrome (SRNS) with or without haematuria clinically and by focal segmental glomerulosclerosis (FSGS) lesions, particularly its collapsing variants and rarely diffuse mesangial sclerosis, histopathologically. Light microscopic findings are not specific; however, although not always visible in electron microscopy, high numbers of dysmorphic mitochondria in the cytoplasm of podocytes might be indicative of an underlying mitochondrial disease [1]. After the identification of the first link between CoQ_{10} deficiency and renal disease in the year 2000 [14], several genes involving endogenous CoQ_{10} biosynthesis including *COQ2, COQ6, COQ8B, PDSS1, PDSS2,* and *COQ9* have been discovered to cause mainly glomerular but rarely tubular disorders when mutated and altogether are responsible for 1% of SRNS (Table 1) [9, 15].

COQ2 Nephropathy

COQ2-encoding 4-para-hydroxybenzoate polyprenyltransferase, an enzyme that catalyzes the second step in the mitochondrial biosynthesis of endogenous CoQ_{10}, was the first gene defect linked to primary CoQ_{10} deficiency [16]. It is a rare disorder, with 27 patients with biallelic *COQ2* variants reported in the literature to date [17, 18]. The disease manifests with three clinical presentations: (a) isolated nephrotic syndrome, (b) cerebrorenal disease, and (c) multisystemic disease. Reported extrarenal findings include progressive ataxia, generalized amyotrophy, retinitis pigmentosa, nystagmus, bilateral SNHL, psychomotor delay or progressive psychomotor regression, optic atrophy, hypotonia, seizure, acute respiratory distress, hypertrophic cardiomyopathy, liver failure, anaemia, pancytopaenia, insulin-dependent diabetes mellitus, and metabolic acidosis [9]. Onset is usually before the age of 2.5 years, but adolescent onset SRNS has also been reported [19]. In the initial reports of COQ2 deficiency, CoQ_{10} supplementation was suggested to improve neurological symptoms but not the renal findings. However, these initial patients had advanced kidney disease at the time of commencing CoQ_{10} supplementation, and subsequent studies showed beneficial effects of CoQ_{10} supplementation on proteinuria if started immediately after onset of renal symptoms [17, 18, 20] but no improvement of progressive encephalopathy [17].

COQ6 Nephropathy

COQ6 encodes a monooxygenase enzyme that catalyzes the C5 hydroxylation step of the quinone ring during endogenous CoQ_{10} biosynthesis [9]. To date, 21 patients with biallelic *COQ6* variants have been reported. The main clinical presentation is progressive SRNS resulting in end stage kidney disease (ESKD) and SNHL. The median age of diagnosis is 1.2 (range 0.2–7) years [21]. Extrarenal findings including seizure, white matter abnormalities, ataxia, facial dysmorphism, growth retardation, muscle weakness, exotrophia, nystagmus, and bilateral optic nerve atrophy have been reported [22]. Untreated, ESKD develops between 0.4–9 years of age. Exogenous CoQ_{10} supplementation may be beneficial and should be considered for protecting renal function; however, its beneficial effect on SNHL and other extrarenal findings does not seem to be promising [9, 21].

PDSS1 and PDSS2 Nephropathies

PDSS1 encodes decaprenyl-diphosphate synthase subunit 1, which is required for the synthesis of the polyisoprenoid chain, while *PDSS2* encodes decaprenyl-diphosphate synthase subunit 2, which is required for the elongation of the prenyl side chain during biosynthesis of CoQ_{10}. These disorders are extremely rare, manifest as infantile-onset multisystemic disease, and are generally fatal despite exogenous CoQ_{10} therapy. In 2000, three siblings with similar symptoms but different degrees of severity characterized by nephrotic syndrome, ataxia, dystonia, muscle weakness, retinitis pigmentosa, SNHL, and cardiomyopathy were reported in whom *PDSS2* mutation as an underlying etiology was subsequently identified [14, 23]. Since then, *PDSS2*-related disorders have been reported in four further patients, all with SRNS [15, 24, 25]. Associated findings in these patients include neonatal pneumonia, hypotonia, seizure, changes in the basal ganglia consistent with Leigh syndrome, encephalomyopathy, hypertrophic cardiomyopathy, SNHL, and retinitis pigmentosa. *PDSS1*-related nephropathy has been described in only one patient with infantile SRNS, developmental delay, leukoencephalopathy, lactate peak, and faltering growth [26].

COQ8B Nephropathy

COQ8B (previously known as *ADCK4*) encodes an atypical kinase that interacts with components of the CoQ_{10} biosynthesis pathway. Patients with *COQ8B* mutations have reduced cellular CoQ_{10} content [27]. Among the CoQ_{10}-related nephropathies, recessive mutations in *COQ8B* account for the highest number of patients and constitute an important differential diagnosis in adolescents with SRNS/FSGS and/or chronic kidney disease (CKD) of unknown origin [28, 29]. The renal phenotype of *COQ8B* disease is characterized by an insidious onset at adolescence with mild-to-moderate proteinuria and absence of apparent edema in the majority of cases. As a consequence of the oligosymptomatic early course, advanced CKD is often present at the time of diagnosis. Haematuria may be present at presentation in 25% of patients, and FSGS is the main histopathological diagnosis [28]. In contrast to other CoQ_{10} deficiencies, *COQ8B* disease typically manifests as an isolated nephropathy with only occasional extrarenal symptoms, which have been described in only a few patients and include seizure, intellectual impairment, defects of visual field, retinitis pigmentosa, agoraphobia, hypertrophic cardiomyopathy, autism, and pulmonary hypertension [28, 29]. Although clinical presentation is not usually seen until the adolescent period, asymptomatic proteinuria may actually be present at any age between 4.4 and 39 years [29]. *COQ8B*-related nephropathies are among the CoQ_{10} deficiencies that appear to benefit most from exogenous CoQ_{10} supplementation. In animal models, knocking out *Coq8b* resulted in reduced podocyte motility in vitro, which could be reversed by adding CoQ_{10} to the culture medium [27]. In humans, exogenous CoQ_{10} supplementation has been shown to decrease proteinuria while preserving glomerular filtration rate [27–30]. In view of its insidious nature, screening of apparently asymptomatic individuals for early diagnosis and avoidance of progressive renal disease by early initiation of CoQ_{10} treatment are recommended in families with at least one affected individual with *COQ8B* nephropathy [29, 30].

COQ9 Nephropathy

COQ9 is necessary for the stability and function of COQ7. Mutations in *COQ9* are extremely rare and have been reported in only a few individuals. Reported findings include neonatal lactic acidosis, intractable seizures, global developmental delay, microcephaly, dystonia, left ventricular hypertrophy, Leigh-like syndrome, truncal hypotonia, dysmorphic features, cardiomyopathy, tubulopathy, abnormal appearing kidneys, and cystic kidneys [9, 31]. Limited clinical benefit of exogenous CoQ_{10} supplementation was observed in these patients.

Other Nuclear-Encoded Mitochondrial Disorders Associated with Renal Involvement

Approaching 1500 nuclear-encoded proteins are needed for mitochondrial function, and more than 350 of these have now been linked to mitochondrial disease [2]. In addition to the CoQ_{10} biosynthesis disorders described above, pathogenic variants in dozens of nuclear genes have been reported to cause significant renal dysfunction, usually in the context of complex multisystem disorders presenting in childhood [32]. Renal manifestations of these gene defects include tubulopathy, ESKD, nephrocalcinosis, and congenital kidney abnormalities. Detailed discussion of all of these gene defects is beyond the scope of this chapter, but we describe the pathological mechanisms of nuclear-encoded mitochondrial disease and some of the more common disorders linked to renal manifestations.

Disorders of OXPHOS Subunits and Assembly Factors

Mutations of nuclear-encoded structural OXPHOS proteins have rarely been reported to cause renal disease. Exceptions include two complex III subunits, UQCC2 and UQCRC2, mutations of which have been linked to tubular dysfunction and neonatal-onset lactic acidosis [33, 34]. Mutations of a complex V subunit ATP5A1 caused a fatal neonatal encephalopathy with renal cysts [35].

The complex nature of the OXPHOS enzymes means that their assembly is an intricate process involving many assembly factors. Renal tubulopathy has been documented in defects of the assembly of complexes I, III, IV, and V (Table 1). The most prevalent of these disorders is BCS1L deficiency, a disorder of complex III assembly that has been linked to a wide clinical spectrum. The most severe phenotype of BCS1L deficiency is GRACILE (Growth Retardation, Aminoaciduria, Cholestasis, Iron overload, Lactic acidosis, and Early death) syndrome, but tubulopathy is a frequent feature in patients with *BCS1L* mutations leading to other clinical presentations, typically including encephalopathy and hepatopathy [36]. Mutations of two factors needed for complex V assembly have also been reported to cause renal manifestations. An infant with ATPAF2 deficiency had hypoplastic kidneys [37], while renal involvement was present in 34% of a large cohort of children with biallelic variants in *TMEM70*, in association with neonatal onset cardiomyopathy, lactic acidosis, hyperammonaemia, and 3-methylglutaconic aciduria, with a progressive neurological course [38].

Mitochondrial DNA Maintenance Defects

Disorders of mtDNA maintenance may be divided broadly into defects of the mitochondrial replication apparatus and defects of nucleoside supply for mtDNA synthesis. Mutations of *POLG* encoding the catalytic subunit of DNA polymerase gamma, the only enzyme able to replicate mtDNA, are the most prevalent single gene cause of mitochondrial disease. *POLG* mutations result in mtDNA depletion and/or multiple mtDNA deletions and present with neurological disease, usually epilepsy, ataxia, or ophthalmoplegia but can occasionally be associated with renal tubular acidosis [39]. Two defects of mitochondrial nucleoside salvage, DGUOK and MPV17 deficiencies, cause mtDNA depletion syndromes manifesting with liver failure, encephalomyopathy, and renal tubulopathy [40, 41]. A third disorder, RRM2B deficiency, is a defect of cytosolic de novo nucleoside synthesis. Infantile-onset RRM2B deficiency now appears to be a relatively homogeneous condition with neonatal onset muscle weakness leading to feeding difficulties and respiratory failure, frequently associated with SNHL and gastrointestinal manifestations, and with renal tubulopathy reported in 55% of cases [42].

Disorders of Mitochondrial Translation

The burgeoning group of disorders of mitochondrial gene expression, which includes defects of mitochondrial RNA modification, aminoacyl tRNA synthetases, ribosomal proteins, and translation elongation factors, is frequently accompanied by renal manifestations (Table 1). Mutations of *SARS2*, encoding the mitochondrial aminoacyl tRNA synthetase for serine, were initially linked to a syndrome of hyperuricemia, pulmonary hypertension, and renal failure in infancy with alkalosis (HUPRA) [43] but more recently have been reported to cause spastic paraparesis without renal involvement. Defects of several other mitochondrial aminoacyl tRNA synthetases are associated with tubular dysfunction, as are mutations of four mitochondrial ribosomal proteins (Table 1). One of the most frequently reported mitochondrial translation defects resulting in ESKD is RMND1 deficiency, which initially manifests with a neonatal pseudohypoaldosteronism type picture associated with SNHL, with later progressive renal disease associated with myopathy and lactic acidosis [44].

Defects of Mitochondrial Lipid Membranes and Dynamics

Another growing subgroup of mitochondrial disorders includes defects of proteins needed for the synthesis of mitochondrial membrane lipids and for mitochondrial dynamics (fission and fusion). SERAC1 deficiency, a defect of mitochondrial membrane lipid remodelling, causes a syndrome of 3-methylglutaconic aciduria, deafness, and Leigh-like encephalomyopathy (MEGDEL). Impaired tubular function was noted in the neonatal period in 12% (8/66) of cases in one large series of patients with *SERAC1* mutations, and was a transient problem in most cases, who went on to have a progressive neurodegenerative disorder dominated by dystonia (Table 1) [45].

Disorder of Iron-Sulfur Cluster Biosynthesis

Iron-sulfur (Fe-S) clusters are essential components of several mitochondrial enzyme complexes, and numerous defects of Fe-S cluster biosynthesis have been linked to mitochondrial disease. Examples of Fe-S cluster defects associated with renal disease include NFS1 deficiency, which was reported to cause ESKD in two infants (Table 1) [46].

Other Disease Mechanisms

Novel molecular mechanisms of mitochondrial disease are increasingly recognized, and frequently associated with renal abnormalities. For example, mutations of *TRAP1*, encoding tumor necrosis factor receptor-associated protein 1, a mitochondrial chaperone, have been linked to congenital abnormalities of the kidney and urinary tract (CAKUT) and VACTERL association [47]. Deficiency of CLPB, an enzyme needed for mitochondrial homeostasis, was reported to cause cataracts, renal cysts, and nephrocalcinosis with 3-methylglutaconic aciduria [48] but has also been linked to more complex infantile onset multisystem disorders, occasionally with ESKD [49]. Mutations of *C1QBP*-encoding complement component 1 Q subcomponent-binding protein caused mitochondrial cardiomyopathy with congenital nephrosis in one case (Table 1) [50]. Other disease mechanisms associated with mitochondrial kidney disease include mitochondrial toxicity and disorders of antioxidant defense.

Approach to Diagnosis of Mitochondrial Kidney Disease

The diagnosis of these conditions remains complex. Routine renal histology is usually not specific for mitochondrial diseases. It is possible to perform histochemical studies assessing cytochrome *c* oxidase and succinate dehydrogenase activities on frozen sections, similarly to what is routinely performed on skeletal muscle samples. These tests, however, have never gained popularity, partly due to technical issues, and in part because abnormal histochemical staining patterns are often observed in acquired disorders. Electron microscopy can be useful to exclude other conditions, particularly Alport syndrome. The presence of abnormally shaped mitochondria in podocytes and/or tubular cells, or signs of mitochondrial proliferation, may provide important clues to the diagnosis [51].

Next generation sequencing has revolutionized the diagnosis of Mendelian disorders, including nuclear-encoded mitochondrial disorders. It is now possible to study panels comprising hundreds of genes in a nuclear mitochondrial gene panel, which can also be adapted to capture the mtDNA. Furthermore, reduction in costs is making the analysis of the entire exome or genome a realistic alternative in the routine diagnostic setting.

The identification of causative mtDNA mutations can be more problematic due to heteroplasmy and random drift events. However, next generation sequencing is also an attractive tool for analyzing low-level heteroplasmic mtDNA mutations. The high throughput allows great breadth of coverage (analyzing whole mtDNA genomes across multiple samples) and great depth of coverage (resolution of very low-level variants).

Analysis of DNA extracted from muscle was considered the gold standard, but it requires an invasive procedure. In recent years, analysis of DNA extracted from urinary sediment cells has become popular. It is possible to screen for mtDNA deletions and for the common point mutations, or sequence the entire mitochondrial genome.

Management and Treatment

Individuals with mitochondrial disorders should be managed by a multidisciplinary team depending on the spectrum of renal and extra-renal findings. Early diagnosis is particularly important for CoQ_{10}-related disorders as early supplementation of CoQ_{10} may prevent these individuals from progressive disease. No evidence-based study regarding dosage has been published. Therefore, CoQ_{10} has been given to patients with empirical doses 30–50 mg/kg per day [9, 20, 29, 30]. Since the bioavailability and the correlation between plasma and tissue levels of CoQ_{10} are poor, observing clinical response is the only practical method to monitor the efficacy of therapy. Regular surveillance for and supportive management of extrarenal manifestations is important; such supportive measures may include antiepileptic drugs, hearing aids, cochlear implants, brow suspension for ptosis, pacing for heart block, medical management of cardiomyopathy, blood transfusions in Pearson syndrome, hormone replacement, and appropriate nutritional support.

Abstract

Fabry disease is a rare lysosomal storage disorder, caused by the deficiency of the enzyme alpha-galactosidase A that is responsible for the degradation of the sphingolipid globotriaosylceramide, also called Gb3. Due to the insufficient activity of alpha-galactosidase-A, Gb3 accumulates in a variety of cells of the body, resulting in progressive organ damage. Fabry disease is an X-linked disorder in which also females are affected, although often less severely than males. Clinically, this multisystemic disorder is characterized by neuropathic pain, gastrointestinal disturbances, typical skin lesions, sweating difficulties, and kidney and heart failure. Life expectancy is

significantly reduced, whereby in both males and females, renal and cardiac diseases are the primary causes of death. In children, pain in hands and feet (acroparesthesia) and abdominal cramps are the leading symptoms; further clinical manifestations include corneal opacities, called cornea verticillata, and skin abnormalities (angiokeratoma). Albuminuria and an increased heart size represent the first signs of renal and cardiac manifestation that can be present already in young patients. Besides symptomatic and supplementary treatment such as analgesics, drugs for kidney dysfunction and for blood pressure control, enzyme replacement therapy is available for children with Fabry disease.

Keywords

Acroparesthesia · Alpha galactosidase A · Angiokeratoma · Cornea verticillata · Enzyme replacement therapy · Fabry disease · Globotriaosylceramide · Lysosomal storage disorder · Sphingolipid · X-linked disorder

Pathophysiology and Genetics

Fabry disease is an X-linked sphingolipid storage disorder caused by the deficiency of the lysosomal enzyme alpha-galactosidase A. Sphingolipids are complex lipids in which to the hydrophobic ceramide (composed of the long-chain sphingoid and a fatty acid) monosaccharides are bound. They are major components of cell membranes and have signaling and regulatory functions [1]. The sphingolipid globotriaosylceramide (Gb3) is composed of ceramide and the monosaccharides glucose and galactose; it is degraded within the lysosomes by the enzyme alpha-galactosidase A (Fig. 1). A genetic defect of this enzyme leads to the accumulation of Gb3 in various cell types such as endothelial cells, different kidney cells, and cardiac and nerve cells. The occurrence of the storage material in a great number of tissues and organs explains the multisystem character of Fabry disease. Aerts and colleagues have found that the level not only of Gb3, but also of the deacylated form, namely globotriaosylsphingosin (LysoGb3), is increased in several organs of Fabry patients and seems to play an important role in the pathogenesis of this lysosomal storage disorder as it inhibits alpha-galactosidase A activity and promotes proliferation of smooth muscle cells [2].

Alpha-galactosidase A is encoded by the *GLA* gene that was mapped to the long arm of the X-chromosome in the region Xq22.1 and contains seven exons. More than 960 pathogenic variants have been described in the *Human Gene Mutation Database (HGMD)*, whereby most of them (75%) are point mutations, and only a few (about 5%) encompass the splicing region [3].

The degree of X-chromosome inactivation (XCI) plays an important role in the phenotypic expression of females with Fabry disease: XCI is a mechanism that takes place in early female development by which one of the two X-chromosomes is inactivated in order to achieve gene dosage equivalence between females and males who carry a single X-chromosome. This process results in an average inactivation ratio of 50:50 with normal distribution. However, a percentage of females will have – without any obvious reason – unequal (skewed) XCI with a preferential inactivation of the same X-chromosome. Therefore, the disease severity and progression in Fabry females depends – at least in part – from the ratio of wild-type to mutated X-chromosome inactivation [4, 5].

Fabry disease is a rare condition, but probably the most frequent lysosomal storage disorder in humans. Formerly, the incidence has been estimated to range from 1 in 40,000 to 1 in 117,000 male live births [6]. A number of newborn screening studies have been performed in the last few years, however, and revealed that Fabry disease seems to be much more prevalent than it was anticipated from former observations. The prevalence, calculated from these studies, ranges from 1/1100 boys in Italy to 1/7057 (boys and girls) in Japan [7]. It has to be taken into account, however, that, in general, newborn screening detects more

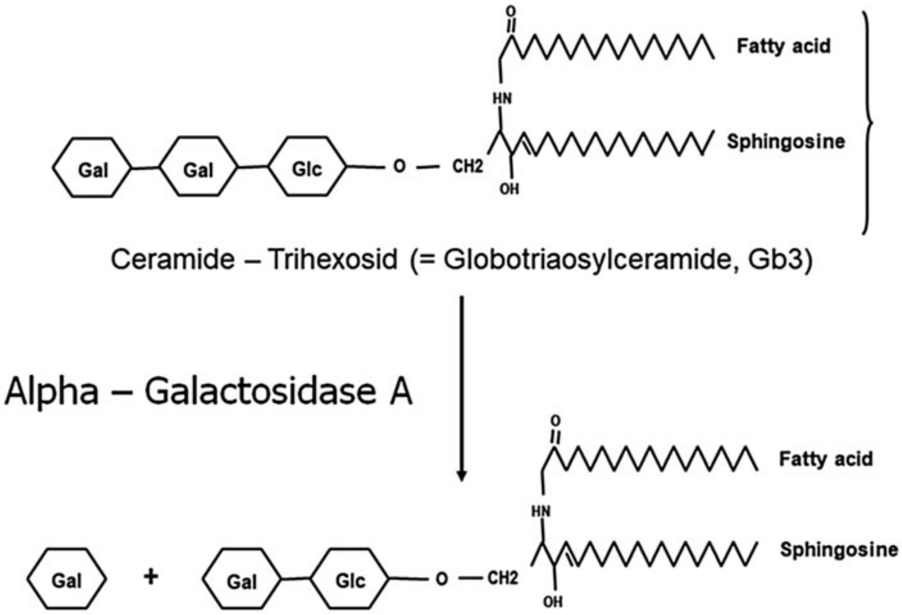

Fig. 1 Alpha galactosidase A splits galactose off the sphingolipid globotriaosylceramide (Gb3)

cases of a late-onset phenotype than those of a classic phenotype [8].

Clinical Manifestations

Neuropathic Pain and Gastrointestinal Symptoms

Peripheral neuropathy represents the first striking symptom in children with Fabry disease, which can be explained by Gb3-accumulation in vasa nervorum and small nerve axons, leading to degeneration of small unmyelinated fibers [9]. Boys and girls complain of pain, often associated with fever and reduced heat and exercise tolerance. Pain, in Fabry disease is also called acroparesthesia, described as burning, often associated with a deep aching sensation [10]. In boys, acroparesthesia can occur already at the age of 3 years [10].

Accumulation of Gb3 in autonomic small fibers explains other clinical manifestations of Fabry disease that are seen already in childhood: hypohydrosis, reduced heart rate variability, and gastrointestinal disturbances such as abdominal cramps, diarrhea, and nausea.

Angiokeratomas

The first characteristic skin abnormality (angiokeratomas) can be seen at the age of about 6 years. Angiokeratomas are vascular anomalies of the superficial vascular plexus that form dark red to black papules or nodules covered by epidermal hyperplasia (hyperkeratosis). In childhood, angiokeratomas can be very discrete, for example, surrounding the umbilicus, and in adults they are present at the buttocks, lower back, and genitalia (Fig. 2). Angiokeratomas can be seen also on limbs, hands and feet, and lips.

Eyes and Ears

A specific ophthalmological manifestation of Fabry disease is represented by the condition, cornea verticillata, which can be noted even in patients below 5 years of age. Cornea verticillata consists of

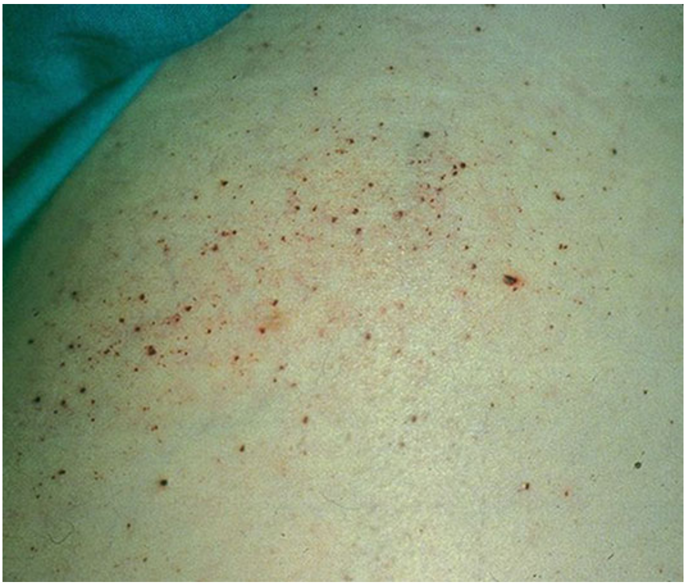

Fig. 2 Angiokeratomas at the back

whorl-like opacities, located in the superficial corneal layer. It usually does not lead to visual impairment. Other ocular changes include tortuosity of retinal vessels and lens cloudiness. Kalkum and colleagues demonstrated that children with eye findings were more severely affected than those without ocular manifestations [11].

Sensorineural and conductive hearing loss is rather common in Fabry disease and may be present in childhood. The involvement of the auditory system can be explained by hyperplastic mucosa and seropurulent effusions of the middle ear and Gb3 accumulation in vascular endothelial and various ganglion cells [12]. An analysis of audiograms of 47 pediatric patients with Fabry disease revealed that affected boys and girls showed increased hearing thresholds at all frequencies, compared to healthy children, in particular at ultrahigh frequency. Five patients had sensorineural hearing loss [13]. Tinnitus and vertigo can be also observed in children with Fabry disease [10].

Kidney

Renal involvement represents the main cause of morbidity and mortality in Fabry disease. Clinical features of Fabry nephropathy have been well known for many years. Proteinuria develops as the first clinical sign in childhood and adolescence, followed by continued decline of kidney function and often reaching end-stage kidney disease (ESKD) in the fourth or fifth decade of life [14].

Analysis of renal biopsies from children reveals storage material in all endothelial cells, in glomerular mesangial cells and podocytes, in distal tubular cells and vascular smooth muscle cells (Fig. 3a, b). It is remarkable that Gb3 accumulation in podocytes is detectable in patients with normal glomerular filtration rate (GFR) and before the development of pathological albuminuria [15]. Histological investigation demonstrates Gb3 accumulation even in the fetal kidney tissue at 19 weeks' gestation, many years before deterioration of kidney function can be found [16].

Heart

The cardiac manifestations of Fabry disease also begin in childhood. Echocardiographic evaluation, performed in 20 children and adolescents under the age of 18 years, revealed that all patients had a left ventricular mass, indexed to height ($LVM/h^{2.7}$), above the 75th percentile of that of healthy controls; yet, blood pressure was in the

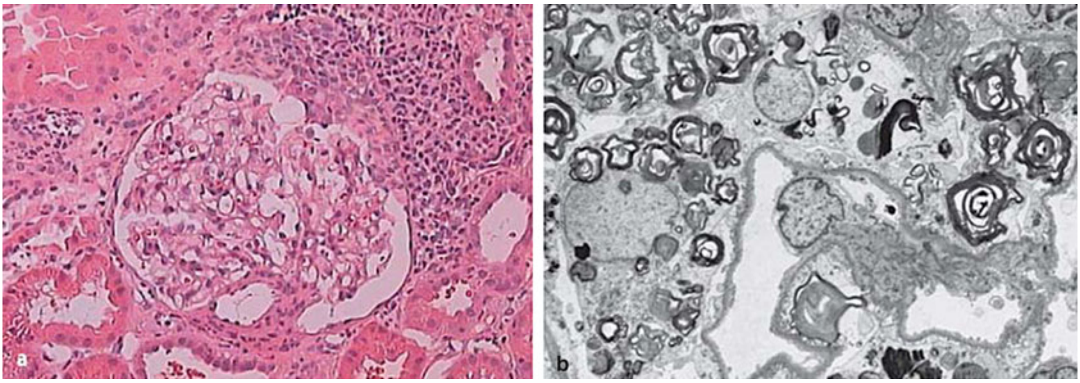

Fig. 3 Kidney biopsy of a Fabry patient (From: [31], with permission). (**a**) The foamy material within glomerular structure represents deposition of Gb3 inclusions that were removed by the embedding process. (**b**) Electron microscopy picture: Osmiophilic zebra bodies in podocytes and glomerular endothelial cells

normal range [17]. Two-hour Holter electrocardiography revealed significantly reduced heart rate variability in males, but not in females, indicating a reduction in parasympathetic stimulation of the heart. Further clinical features that may appear already in young patients include arrhythmias, chest pain, and valvular disease, including mitral valve prolapse [10].

Central Nervous System (CNS)

Stroke and transient ischemic attacks (TIAs) are very common in adult males and females with Fabry disease and are probably caused by a combination of endothelial dysfunction and abnormal function control of the vessels. Whereas cerebrovascular events seem to be very rare in childhood, other symptoms of CNS manifestation such as poor cognitive and executive functioning are apparently more common [18].

Diagnosis

The diagnosis of Fabry disease is made rarely in children, because the first symptoms such as pain and gastrointestinal complaints are rather unspecific, and not every pediatrician is familiar with this rare storage disorder. Therefore, in families with at least one relative with Fabry disease, systematic screening of children must be performed. In boys, the diagnosis can be easily confirmed by measurement of alpha-galactosidase A preferably in leukocytes, but also in plasma or a dried blood spot. In order to confirm the diagnosis in girls, analysis of the *GLA* mutation, which is already known in the affected family members, is necessary, as in affected females the enzyme activity, measured in leukocytes, is often normal.

Due to the lack of specific symptoms, it is often very difficult to make the clinical diagnosis in children of families in which no further Fabry case is known. The combination of burning pain in hands and feet together with sweating difficulties and gastrointestinal symptoms should raise the suspicion of Fabry disease. Also, angiokeratomas may provide an indication of Fabry disease, although it has to be taken into consideration that this skin abnormality is not specific as it can be observed also in other lysosomal storage disorders such as fucosidosis or sialidosis, as well as in apparently healthy individuals [19].

Many patients experience a previous misdiagnosis such as rheumatological disease, arthritis, erythromelalgia, or a neuropsychological disease. Whereas in boys the suspicion of Fabry disease can be confirmed rapidly by enzyme assay, in girls the diagnosis can be more difficult: As noted above, normal enzyme activity does not exclude Fabry disease; therefore, mutational analysis is necessary. If, however, the molecular study reveals a variation of unknown significance, additional clinical and biochemical investigations become necessary. A slit-lamp examination should be performed in order to check for the presence of cornea verticillata, which can be found in about two-thirds of girls [10].

In the past, increased plasma or urinary concentrations of Gb3 were used as a biomarker to monitor progression of Fabry disease. In several studies, however, it has been found that Gb3 concentrations are a poor reflection of the degree of clinical manifestations and therapeutic outcome. Presently, LysoGb3 concentrations are used for the diagnosis and treatment monitoring in Fabry disease. As serum LysoGb3 is significantly elevated not only in males, but also in affected females, it represents a better biochemical diagnostic marker for the identification of Fabry heterozygotes [20]. If the diagnosis of Fabry disease is made in an individual, genetic counseling including pedigree analysis of the whole family is mandatory.

Treatment

General Remarks

Fabry disease is a multisystemic disorder that requires comprehensive and multifaceted management. The establishment of a multidisciplinary team is recommended and should include a pediatric nephrologist, pediatric cardiologist, pediatric neurologist, and other specialists such as a gastroenterologist or psychologist. The coordinator of the team may be a pediatrician or geneticist. Examinations and treatment of the children should be preferably performed in a center that has experience in the management of Fabry disease.

Pain and Gastrointestinal Symptoms

Recommendations regarding the usage of different drugs for the treatment of Fabry-related pain in children are derived from the experience of adult patients with polyneuropathy, trigeminal neuralgia, and other neuropathic conditions. Pain medication should be started at low dose and escalated slowly to therapeutic or adverse effect. Anticonvulsants are commonly used for treatment of Fabry-related pain. Carbamazepine, alone or in combination with pregabalin or gabapentin, can be the first choice of treatment in Fabry disease. One should be aware, however, that carbamazepine bears the risk of exacerbation of autonomic dysfunction. Antidepressants such as venlafaxine or duloxetine are also feasible alternatives. Tricyclic antidepressants should be used with caution because of their anticholinergic effects and the potential to worsen autonomic symptoms [21].

Gastrointestinal problems such as nausea, vomiting, and diarrhea, which are common and important early symptoms in Fabry disease, respond very well to enzyme replacement therapy [22]. Additionally, dietary restrictions and eating small frequent meals are recommended.

Skin

Laser therapy is a consideration for the treatment of angiokeratomas. The results of various laser methods, however, have been mixed or discouraging, and laser therapy may lead to scars and does not prevent the formation of new lesions [23].

Eyes and Ears

The corneal opacity (cornea verticillata) is of diagnostic value but does not impair vision; therefore, any treatment is not required. Audiological investigation should be performed yearly, for the management of hearing loss, and hearing aids or even cochlear implants should be applied.

Kidney

A comprehensive evaluation of kidney function is needed that should include measured GFR (mGFR) and estimated GFR (eGFR) in all children with Fabry disease. As at early stages of progressive renal disease eGFR formulae using serum creatinine are relatively inaccurate, a more precise mGFR (iohexol or radionuclide tracers) should be preferred for assessment of kidney function [24]. However, as these methods may be technically difficult in very young children and/or may not be available in every hospital, eGFR may be used for regular assessment of kidney function at diagnosis and thereafter every 6 or 12 months. It is recommended to use at the first visit also mGFR, in addition eGFR, to determine whether the formulae for eGFR are accurate estimates for that individual patient. It is important also to measure urinary albumin and protein excretion at each visit, as the presence of pathological albuminuria or proteinuria is sufficient to indicate the diagnosis of chronic kidney disease, even in the presence of normal GFR. However, it is clear that normal GFR and urinary protein and albumin levels do not exclude a progressive kidney injury [15]. Although a renal biopsy can show early pathological changes of the kidney, it has not been proven that initiation of treatment based on histopathological findings can improve clinical outcomes. However, a kidney biopsy is mandatory if a decline in kidney function or a substantial increase of protein excretion raises the suspicion of the presence of a concomitant disease, for example, an IgA- or IgM-nephropathy [25, 26].

For the treatment of pathological proteinuria, angiotensin-converting enzyme (ACE) inhibitors or angiotensin receptor blockers (ARB) can be used.

Heart

As mentioned in section “Heart,” cardiac complications such as left ventricular hypertrophy, arrhythmias, and valvular disease can occur in children with Fabry disease. Echocardiography and ECG should be performed at each clinical visit. The Holter test is necessary only if an abnormal rhythm is suspected or palpitations are reported. In order to prevent cardiovascular disease in later life, implementation of healthy lifestyle measures is recommended and should include management of blood pressure and weight control. Other medications, for example, calcium channel antagonists or statins in case of increased lipid levels, and therapeutic procedures such as pacemaker implantation, are in general necessary only in adult patients.

CNS

As the CNS is hardly involved in children with Fabry disease, an MRI should only be performed if a child experiences any neurological change that could be related to a cerebrovascular event. However, as cognitive deficits and depression are not uncommon in young Fabry patients, some children may need psychological support.

Enzyme Replacement Therapy

Enzyme replacement therapy (ERT) seeks to enhance enzyme function in lysosomes by regular intravenous infusions of a genetically engineered recombinant enzyme. In Europe and many other countries, two enzyme preparations are licensed, agalsidase alfa (Replagal®, Shire Takeda), produced in a human cell line, and algalsidase beta (Fabrazyme®, Sanofi Genzyme), produced in a Chinese Hamster Ovary (CHO) cell line. In the USA, only agalsidase beta has received marketing authorization. Although both enzyme preparations are biochemically and structurally very similar, there is a considerable difference in the dosage. The recommended dosage for agalsidase alfa is 0.2 mg/kg every other week (EOW), and for agalsidase beta 1.0 mg/kg EOW. Several studies have demonstrated that treatment with both enzymes can improve or at least delay some of the clinical manifestations such as the pain and kidney and heart dysfunction [27].

Agalsidase alfa and beta are safe and well tolerated in adults and children. Children receiving ERT experience a reduction of neuropathic pain and gastrointestinal symptoms, resulting in an improvement of exercise performance and of quality of life [28]. Kidney biopsies, performed in young patients several years after initiation of ERT, showed clearance of glomerular endothelial and mesangial cell inclusions, and in four patients, who received the highest dose of agalsidase, a substantial clearance of podocyte inclusions could be detected. Albuminuria normalized in some patients [29].

The decision when to start ERT denotes a difficult decision as it has important implications not only for the child, but also for the whole family. A negative impact on social activities, the need for repeated venous access, and the potential for infusion reactions should be taken into consideration. However, these factors should be balanced against the chance of clinical benefits that can be gained from preventing irreversible organ damage or at least reducing disease progression.

There is a general consensus that ERT should be initiated in children as soon they show any major organ involvement, regardless of age or sex. Signs and symptoms that warrant treatment with an enzyme preparation are neuropathic pain, gastrointestinal disturbances, decline in kidney function, pathological albuminuria or proteinuria, and signs of heart involvement (cardiomyopathy or arrhythmia). Whether asymptomatic boys around age 8–10 years should receive ERT, based on the evidence of storage material in a kidney biopsy, prior to the onset of albuminuria or other clinically significant renal findings, remains a matter of debate [15]. Asymptomatic girls with Fabry mutations should be followed closely according to the same schedule of clinical examinations as male patients. They should be treated, however, as soon as they show any clinical manifestation.

Chaperone Therapy

An efficient mechanism exists that controls exact folding of newly synthesized enzymes in each cell. Some missense mutations that do not affect the catalytic site, but the accurate folding of lysosomal enzymes, prevent them from reaching the lysosome, so that they cannot fulfil their function. However, some mutant enzymes might regain at least partial catalytic activity if they could acquire their correct confirmation. The amino sugar migalastat (Galafold®, Amicus Therapeutics) is a competitive inhibitor of the enzyme alpha-galactosidase A that, at subinhibitory concentrations, functions as a so-called chemical chaperone leading to correct confirmation of the mutant enzyme and thereby increasing its catalytic activity. Migalastat is approved for patients 16 years of age and older with an amenable *GLA* variant, which means a mutation that affects not the catalytic site, but the folding of the enzyme [30].

Abstract

Three distinct types of primary hyperoxaluria (PH) have been identified based on molecular genetics and biochemical analyses. All types are characterized by loss of function of key enzymes of the hepatic glyoxylate metabolism. The prognosis of the disease is dependent on the type of PH. PH1 is the most common and the most severe form. Patients with PH1 have a high risk of progressing to end-stage kidney disease (ESKD) and of developing systemic manifestations related to oxalate depositions in tissues (systemic oxalosis). In comparison, PH2 carries an intermediate risk of kidney failure, usually in adulthood, and a lower risk of systemic oxalosis. PH3 is the most favorable form; ESKD has only been reported anecdotally in PH3, and, remarkably, symptomatic adults are rarely diagnosed.

Measurement of urinary oxalate and genetic testing allow screening and rapid diagnosis of PH. Precise genotyping has important therapeutic implications. RNA interference treatment represents one of the first examples of precision medicine in nephrology. Nonetheless, hyperhydration and vitamin B6 (pyridoxine) supplementation in susceptible PH1 genotypes continue to represent the mainstay of treatment for many patients. However, effective and affordable treatment for PH remain an unmet need in many areas of the world.

In addition to PH, hyperoxaluria can be secondary to intestinal malabsorption, to ingestion of oxalate precursors, or to specific dietary conditions. Without appropriate measures for prevention and treatment, secondary hyperoxaluria can cause severe kidney function impairment that may progress in some cases to ESKD.

Introduction

Primary hyperoxalurias (PH) are a group of autosomal recessive disorders of glyoxylate metabolism with variable incidence in different regions of the world. This chapter discusses the major biochemical, genetic, and therapeutic advances in these diseases.

The enzymatic defects cause overproduction of oxalate, primarily by the liver, which increases the oxalate load to the kidneys. Oxalate is a highly insoluble end-product of collagen metabolism in humans. The first symptoms are related to hyperoxaluria (i.e., urolithiasis and/or nephrocalcinosis), which progressively impair the glomerular filtration rate (GFR). A second phase of tissue damage develops when the kidneys become unable to excrete the entire oxalate load, causing oxalate depositions in all tissues. This phase is termed systemic oxalosis.

The diagnosis of PH relies on measuring urine oxalate (Uox) excretion and performing genetic tests. This allows classifying most cases of PH into three forms, namely, type 1, 2, and 3 PH. PH1 is the most common and severe form. Rarely, the phenotype remains uncertain and does not correspond to a known PH subtype from the genetic standpoint.

Current management includes conservative measures, which for many years were followed by combined liver-kidney transplantation in PH1. New therapeutic approaches targeting the glyoxylate pathway in the liver have recently been developed and are likely to delay in the future chronic kidney disease (CKD) progression in all types of PH and to replace liver transplantation in PH1.

Secondary hyperoxaluria may occur in conditions characterized by excess of oxalate precursors or increased intestinal oxalate reabsorption (enteric hyperoxaluria), particularly in malabsorption syndromes. Excess dietary intake has also been reported to cause secondary hyperoxaluria. Secondary hyperoxaluria must be excluded in all patients investigated for PH.

Definition

Oxalate is the dianion of oxalic acid (HOOC-COOH), an organic acid with a molar mass of 90 g.mol^{-1} in its anhydrous form. Measurement of Uox excretion in a timed-urine collection (preferably 24 h) is the gold standard to diagnose hyperoxaluria (Table 1). In infants and young children, spot urine samples may be used to measure the Uox:Ucr (urinary creatinine) ratio. The Uox:Ucr ratio is a reliable screening method, but results must be interpreted according to age (Table 1). Uox can be measured with enzymatic methods, using commercially available kits, liquid chromatography (LC), and gas chromatography after derivatization (GC). Enzymatic methods have the advantage of being easily automatized. Chromatographic methods are more laborious but allow simultaneous assessment of oxalate and citrate (LC) or oxalate and glycolate (GC). In all types of PH, the level of Uox excretion tends to correlate with kidney function outcome [3].

In PH, the Uox excretion is usually ≥1 mmol/1.73 m^2/24h, with the normal range being <0.5 mmol/1.73 m^2/24 h (Table 1).

Table 1 Reference values for urinary oxalates excretion [1, 2]

Uox:Ucr ratio	
<2 months	<0.28 (mmol/mmol)
2 months–2 years	<0.14 (mmol/mmol)
2 years–12 years	<0.10 (mmol/mmol)
>12 years	<0.08 (mmol/mmol)
24 h Uox excretion	
All ages and sex	<0.5 mmol/1.73 m^2/24 h
Adult male	0.08–0.49 mmol/24 h
Adult female	0.04–0.32 mmol/24 h

Uox, urinary oxalate

Primary Hyperoxalurias

Primary hyperoxalurias are rare inherited disorders of glyoxylate metabolism characterized by increased excretion of Uox leading to recurrent renal stone formation, nephrocalcinosis, and ultimately kidney function impairment. When advanced kidney failure develops, deposition of nonsoluble oxalate in tissues rapidly occurs, causing systemic oxalosis [1].

Three distinct genetic types of PH have been described, namely, PH1, PH2, and PH3. The overall prevalence is 1 per 58,000, based on population analysis approaches [4]. Approximately 70% of patients have PH1, 10% have PH2, and 10% have PH3. In the remaining 10% of patients, a genetic cause cannot be identified. The relative proportion of the different types of PH vary slightly in different regions of the world.

Metabolic Defects

PHs are rare disorders of the glyoxylate metabolism in the liver, causing excessive endogenous production of oxalate. PH per se is not a kidney disease, but since the kidneys are responsible for oxalate clearance, PHs manifest predominantly as a kidney and urinary tract disease, with recurrent nephrolithiasis and/or nephrocalcinosis.

All subtypes of PH are inherited in an autosomal recessive mode and are secondary to the loss of function of the mutated enzyme. Figure 1 summarizes the main metabolic pathways involved in PHs.

Oxalic acid is found in virtually all dietary products in quantities that depend on the source and processing of the product. The oxalate content of a balanced diet does not represent a health issue in the absence of conditions that cause secondary hyperoxaluria.

It is always important to differentiate PHs, which are rare conditions that do not respond well to dietary restrictions, from secondary hyperoxalurias, which are more frequent and potentially treatable with dietary adjustments. Sometimes, this can be challenging in the absence of genetic investigations.

Despite the ability of kidneys to filter efficiently high amounts of small compounds such as oxalate, poor solubility of oxalate in water and high concentration of other solutes in renal tubules limit the solubility of calcium oxalate (CaOx), causing precipitation of insoluble CaOx crystals in patients with PHs. Progressively, interstitial tissue deposition of CaOx occurs, causing severe inflammatory responses that eventually lead to fibrosis and ESKD.

Genetic Analysis

A clinical and biochemical suspicion of PH always requires genetic confirmation, which can be performed using targeted sequencing (Sanger)

or next-generation sequencing (NGS, gene panels/whole exome) of the three causative genes: *AGXT* (PH1), *GRHPR* (PH2), and *HOGA1* (PH3). Since there is only modest genetic heterogeneity in PH and all involved genes are small, targeted Sanger sequencing remains a fast and cost-effective approach.

Defining the type of PH has important prognostic and therapeutic consequences. It defines the possibility of treatment with RNA interference. Some missense mutations (e.g., p.Gly170Arg) of the *AGXT* gene are more likely to respond to conservative treatment with hyperhydration and pyridoxine and are associated with better long-term kidney survival [4–10]. To date, no clear genotype-phenotype correlations has been established in PH2 and PH3 [11, 12]. Genotype information is likely to become increasingly important in future precision medicine approaches.

The prevalence of copy number variations (CNVs) in PH has not been systematically analyzed but appears to be low (<1%; personal communication, B Beck). In rare cases where genetic sequencing identifies only one heterozygous pathogenic variant in patients with a high clinical suspicion of PH, NGS results should be checked for CNVs. Since most heterozygous CNVs would be missed by Sanger sequencing, molecular diagnostics should be complemented by multiplex ligation-dependent probe amplification assay (MLPA) in these patients. MLPA probes are commercially available for *AGXT* and *GRHPR,* but not for *HOGA1* [13].

Alternatively, the expression and enzyme activity of the *AGT, GRHPR,* and *HOGA1* gene products can be tested in tissues obtained from a liver biopsy. This classical methodology has been largely abandoned in favor of noninvasive genetic testing.

Prenatal diagnosis cannot be performed with fetal ultrasonography or by measuring amniotic fluid oxalate concentration. It can only be performed with genetic analysis using noninvasive techniques or DNA specimens obtained from chorionic villi or amniocytes. Prenatal diagnosis can therefore be proposed only to families with index cases that have been genetically characterized. It allows identification of affected and non-affected fetuses.

Primary Hyperoxaluria Type 1

Pathophysiology

PH1 (OMIM 259900) is an autosomal recessive disorder caused by functional defects of the alanine-glyoxylate aminotransferase (AGT) peroxisomal enzyme, leading to oxalate overproduction (Fig. 1). AGT is a liver-specific enzyme that is pyridoxal-5′-phosphate-dependent. Symptoms develop if the AGT activity is insufficient or if AGT is mistargeted to the mitochondria, which may explain enzymatic heterogeneity. The kidneys are the initial target of oxalate overproduction. The first symptoms are related to hyperoxaluria (i.e., urolithiasis and/or nephrocalcinosis), which progressively compromises the integrity of the renal parenchyma, causing CKD and ultimately ESKD. Renal damage is multifactorial, including oxalate-mediated tubular damage, nephrocalcinosis with intratubular and interstitial calcium oxalate (CaOx) depositions, interstitial inflammation and fibrosis, obstruction by stones, and often superimposed infection [1]. A second phase of tissue damage in PH1 occurs when the decline in GFR reaches stage 3 CKD (i.e., 30–59 mL/min per 1.73 m^2). In this condition, the kidneys become unable to excrete the entire oxalate load, causing a rise in plasma oxalate concentration (normal Pox levels: <6 to 17 μmol/L) that exceeds the plasma saturation threshold (around 30 to 40 μmol/L). A multisystem injury secondary to CaOx depositions in virtually all tissues develops; this condition is referred to as systemic oxalosis [14–17]. Bone deposition can be massive, resulting in debilitating pain and fractures (Fig. 2). After kidney transplantation, the mobilization of oxalate from stores can be extremely important, in particular from bones, and may last for months and even years [18]. This can cause deposition of oxalate in the newly transplanted kidney and possibly graft failure, a well-known complication in undiagnosed PH1 patients receiving isolated kidney transplantation [18].

Severe systemic oxalosis is primarily observed in PH1; it is rarely reported in patients with ESKD secondary to other types of PH with moderately elevated Pox levels [15, 19]. Interestingly, the substantial contribution of elevated Pox levels to

the pro-inflammatory state and increased cardiovascular risk of the latter population have not received a lot of attention.

Epidemiology

PH1 is the most common form of PH worldwide. Its clinical incidence in Western Europe approximates 1:100,000 live births per year. PH1 accounts for 1% to 2% of pediatric patients with ESKD, according to registries from Europe, the USA, and Japan. It is significantly more frequent in North African and Middle East nations, where consanguineous marriages are common. In these countries, PH1 is responsible for up to 10% of pediatric ESKD cases and sometimes even more [17, 20, 21]. Twenty to thirty percent of all patients with PH1 present with ESKD at diagnosis [3, 22]. The infantile form often presents as a life-threatening condition. This form is particularly severe because of the combined effects of a very high urinary oxalate load and the immaturity of the kidney function in this age group. Half of these infants have ESKD at the time of diagnosis, and 80% progress to ESKD by the age of 3 years [23, 24]. Unfortunately, the diagnosis is often made too late in most patients with PH, after complications of oxalosis have developed.

Diagnosis and Outcomes

Diagnosis

PH1 should be considered in any child with urolithiasis/nephrocalcinosis and in adults with recurrent CaOx stone events.

The diagnosis is first suspected based on clinical symptoms (Fig. 2). *Patients may present with different clinical pictures*:

- Infants and even neonates with advanced renal failure and nephrocalcinosis. These patients often present with failure to thrive, acute pyelonephritis, vomiting, pallor due to anemia, bone fractures, and other symptoms related to uremia.
- Nephrolithiasis at any age, usually recurrent and bilateral, often associated with decreased GFR.
- When patients reach CKD stage 3, severe extrarenal manifestations may develop [1]:
  - The main site of deposition of oxalate is the skeleton (Fig. 2), leading to pathologic

  fractures, bone deformations, severe bone pains, and a specific oxalate osteopathy on X-ray [25].
  - All organs can be involved: myocardium, retina, joints, vessels, skin, marrow, nerves, liver, brain, thyroid, gonads, etc. [1, 26–30].

The main biomarkers for diagnosis are in the urine:

- Microscopic urine crystal examination and infrared spectrometry show monohydrated calcium oxalate (whewellite).
- Urine oxalate >0.5 mmol/1.73 m^2 BSA per 24-h or Uox:Ucr >0.10 mmol/mmol.
- Urine glycolate >0.5 mmol/1.73 m^2 BSA per 24 h.

Plasma oxalate concentration cannot be regarded as a diagnosis marker, since it is influenced by GFR [31]. The upper limit of the normal range varies between 6 and 17 μmol/L, depending on the methodology [16]. Plasma oxalate measurements are mostly helpful in the follow-up of dialyzed and transplanted patients.

Genotyping is required to confirm the diagnosis of PH1 and to guide treatment.

AGT enzyme activity can be assessed on liver biopsy specimens, but this invasive approach has been replaced by genotyping, which also provides reliable genotype/phenotype correlations.

Outcome

Patients with PH1 often experience acute deterioration of their GFR that may be triggered by urological issues, including acute pyelonephritis, ureteral obstruction, open urological surgery, or extracorporeal lithotripsy, or by non-urological conditions, such as acute dehydration, acute kidney injury of any type of surgery or general anesthesia. PH1 is a devastating disease that leads to ESKD within the first two to three decades of life in most cases.

Treatment: Supportive Measures

Limited supportive measures are available for patients with PH1. They are more efficient if started early, even before confirmation of the diagnosis by genetic testing. Symptomatic treatment relies on continuous hydration over the entire 24 h period, inhibition of CaOx crystallization, and pyridoxine therapy in responsive patients (Table 2) [32–34].

Restriction of dietary oxalate intake (spinach, rhubarb, cocoa, tea, asparagus, star fruit, Swiss chard, etc.) has limited impact because dietary oxalates contribute only marginally to the renal oxalate load in PH. Dietary calcium should not be restricted because calcium binds oxalate in the intestine to form insoluble CaOx complexes that are eliminated in the stools [33]. Ascorbic acid supplementation should be avoided because ascorbic acid is a precursor of oxalate [34, 35].

Dialysis

In principle, dialysis should always be avoided in PH. Nonetheless, dialysis is necessary in patients presenting with ESKD or in those that cannot be treated with transplantation before they need renal replacement therapy [33]. Oxalate is a small molecule, easily cleared by hemodialysis membranes. However, conventional hemodialysis is unable to match the hepatic production (4 to 8 mmol per day in adults); therefore, large amounts of oxalate are stored in the body when patients are treated with dialysis. Intensive dialysis strategies, including daily hemodialysis or combined hemo- and peritoneal dialysis, can remove more oxalate, but the balance remains positive and predialysis Pox levels usually are greater than 100 μmol/L. Theoretically, multiple short hemodialysis sessions per day could balance the oxalate overproduction by the liver, but these are not acceptable in terms of quality of life.

Transplantation

Kidney transplantation restores the kidney function, but only liver transplantation corrects the metabolic defect, preventing recurrence of the disease in the transplanted kidney. Therefore, most patients require a dual liver-kidney transplantation, either simultaneous or sequential (liver first and then kidney), according to the burden of oxalates and to local access to organs [36, 37]. In principle, organ transplantation in PH should always be preemptive to reduce the mortality and the morbidity caused by systemic

Table 2 Supportive measures in patients with PH1 and preserved GFR [33, 34]

GFR, glomerular filtration rate; Ox, oxalate; Uox, urinary oxalate; Uca, urinary calcium

oxalosis. With the new therapeutic approaches (see below), kidney transplantation will probably be postponed in most patients with CKD, and liver transplantation may be restricted to those patients that cannot have access to these treatments.

Treatment: RNA Interfering Agents

RNA interference (RNAi) is a naturally occurring mechanism for regulating gene expression. Small interfering RNAs (siRNAs) allow selective depletion of mRNA molecules that encode for target proteins. In recent years, this technology has been used to develop innovative therapies for PHs.

The first identified target for siRNA therapy was glycolate oxidase (GO). This enzyme is exclusively expressed in hepatocytes and is believed to play a role only in glyoxylate metabolism. GO catalyzes the oxidation of glycolate to glyoxylate, which is the substrate for oxalate synthesis (Fig. 1). By decreasing glyoxylate production, inhibition of GO in PH1 decreases urinary oxalate excretion. The safety of GO suppression in humans was supported by the incidental discovery of GO deficiency in an 8-year-old boy with asymptomatic glycolic aciduria, associated with normal kidney and hepatic functions [38]. Lumasiran, an investigational GO-targeting siRNA, has been recently developed. Targeted delivery of siRNAs to the liver was obtained by conjugation to N-acetylgalactosamine (GalNAc). This allows direct uptake of the drug by asialoglycoprotein receptors, which are exclusively expressed in hepatocytes. The 6-month double-blind phase of a randomized, placebo-controlled phase 3 study evaluating lumasiran in 39 patients with PH1 has recently been completed [39]. The study included children aged more than 6 years and adults with genetically proven PH1 and eGFR >30 mL/min per 1.73 m^2. Lumasiran was administered subcutaneously at 3 mg/kg monthly for 3 months, followed by quarterly doses. The least squares mean change from baseline in 24 h Uox excretion was −65.4% in the lumasiran group and −11.8% in the placebo group. The proportion of lumasiran-treated patients who achieved normalization or near normalization of 24 h Uox excretion at 6 months was 84%, compared to 0% in placebo-treated patients. There were no serious or severe adverse events. The most common adverse event was a mild and transient injection site reaction in 38% of lumasiran-treated patients. Lumasiran has been recently approved by several health technology assessment bodies worldwide.

In addition, nedosiran, a siRNA targeting the lactate dehydrogenase A (LDHA) enzyme, has been recently developed. Similarly to lumasiran, conjugation with GalNAc allows selective silencing of LDHA in the liver, preventing off-target effects in other tissues, especially in muscles. Since LDHA mediates the final enzymatic reaction of oxalate production (Fig. 1), nedosiran can be beneficial in all types of PH. In a phase 1 study including 15 patients with PH1 and 3 patients with

PH2, nedosiran was shown to reduce Uox by 55% from baseline after 57 days, with 6 patients reaching normal 24 h Uox excretion rates [40]. Safety was excellent, with only injection site reactions reported in 5 of the 18 patients.

Treatment: Future Developments

High morbidity and mortality of liver transplantation and the excessive costs of siRNA-based targeted therapies will be the main drivers for the development of future therapeutic options [41]. The range of research and development include gene therapy that allows permanent correction of enzyme deficiencies, identification of pharmacochaperones for amenable (mistargeting) missense mutations, therapeutic targeting of genetic and/or environmental modifiers that have been identified in discordant families and in asymptomatic individuals with biallelic *HOGA1* mutations, and oxalate degrading therapies [42–58]. Development of biomarkers that help identify individuals at increased risk of renal injury and/or systemic oxalosis may allow the development of precision medicine approaches, including multimodal treatment strategies.

Stiripentol, an LDHA-targeted commercially available oral medication for Dravet syndrome, was recently reported to reduce significantly Uox in epileptic patients without PH1 and in one PH1 patient with preserved kidney function [59, 60]. The benefits of this treatment in PH are currently under investigation in a phase 2 clinical trial.

Primary Hyperoxaluria Type 2

Pathophysiology

PH2 (OMIM260000) is caused by complete or nearly complete loss-of-function of a ubiquitously expressed cytosolic/mitochondrial enzyme with glyoxylate/hydroxypyruvate reductase (GR/HPR, EC 1.1.1.26) activity [61]. Analysis of tissue samples from patients with PH2 has shown that the GR/HPR enzyme activity is highest in the liver but is also present in leukocytes and in the kidney [62]. Lack of GR/HPR leads to the accumulation of glyoxylate and hydroxypyruvate, which are metabolized by LDHA to oxalate and L-glycerate, respectively (Fig. 1). This results in overproduction of oxalate and L-glycerate and increased excretion of both metabolites in the urine.

Genetics

The disease is transmitted in an autosomal recessive mode. The *GRHPR* gene encoding for the glyoxylate reductase/hydroxypyruvate reductase is located on chromosome 9q11 [63]. Approximately 50 point mutations or small deletions have been identified, most of them involving the coding region or mRNA splicing [11, 61]. Two of these mutations, namely, c.103delG and c.403_404+2delAAGT, are more common. The former occurs exclusively in white populations, the latter almost entirely in Asian populations [64].

Clinical Presentation

Symptoms of PH2 usually develop in childhood (mean age at first symptom, 3.2 years; mean age at diagnosis, 8.0 years) and are characterized by recurrent stones, nephrocalcinosis, and ultimately CKD. Nephrolithiasis is found in 82.8% of patients [11]. Symptoms are comparable to PH1.

Diagnosis

The diagnosis of PH2 should be considered in every child with urolithiasis/nephrocalcinosis and in adults with recurrent CaOx stone events. In particular, the diagnosis of PH2 should be considered in the presence of hyperoxaluria without hyperglycolaturia, especially when *AGXT* mutation analysis is negative. In addition to hyperoxaluria and sometimes hyperglyceraturia (i.e., L-glycerate >5 μmol/L), the diagnosis of PH2 is based on the identification of pathogenic variants in the *GRHPR* gene.

Treatment and Outcomes

The initial management of PH2 patients relies on the reduction of urinary CaOx supersaturation through adequate daily fluid intake and treatment with inhibitors of CaOx crystallization (cf. PH1, Table 2). However, pyridoxine has no beneficial effect.

As in PH1 patients, oxalosis develops in patients with advanced CKD. The median kidney function survival in a very large cohort of 101 patients was 43.3 years [11]. In this cohort, 11 patients received a kidney transplant (12.3%), and 1 patient had undergone combined liver-kidney transplantation. There are only few other case reports of combined liver-kidney transplantation in PH2 patients that have experienced recurrence of the oxalate nephropathy after isolated kidney transplantation. Since the enzymatic defect is not restricted to the liver, combined liver-kidney transplantation is not systematically recommended in PH2. In the same large cohort of 101 patients, renal outcome did not correlate with genotype, biochemical parameters, or the presence of nephrocalcinosis at presentation [11].

Recently, RNA interference therapy with nedosiran, targeting the LDHA enzyme that mediates the final step of oxalate production (Fig. 1), has been shown to normalize Uox excretion also in PH2 [40]. Early treatment with nedosiran might preserve GFR or postpone kidney transplantation in patients that begin treatment at later stages of the disease.

Primary Hyperoxaluria Type 3

In 2010, mutations in the *HOGA1* gene have been shown to be responsible for a new type of PH, designated as PH3 [65].

Pathophysiology

PH3 (OMIM 613616) results from the loss-of-function of the mitochondrial enzyme 4-hydroxy-2-oxoglutarate aldolase (HOGA). HOGA catalyzes a lyase reaction in the final step of the hydroxyproline catabolism, leading to glyoxylate and pyruvate formation from hydroxy-2-oxoglutarate (HOG) (Fig. 1). Theoretically, loss of HOGA function should abrogate glyoxylate production and consequently should not cause hyperoxaluria, since glyoxylate is the immediate precursor of oxalate. Although the exact mechanism underlying PH3 physiopathology remains elusive, two explanations have been proposed. Both assume the existence of an alternative HOG-aldolase activity, which converts part of the accumulated HOG to glyoxylate. In one hypothesis, accumulation of HOG inhibits GRHPR activity, mimicking PH2 [66]. However, HOG inhibits significantly GRHPR only at millimolar concentrations, while nanomolar concentrations have been observed in liver samples obtained from patients with PH3. In addition, individuals with PH3 excrete normal amount of L-glycerate in their urine, which implies preserved cytosolic GRHPR activity. An alternative explanation is that HOG accumulates in mitochondria and is released into the cytosol, where it is converted to glyoxylate by an alternative cytosolic HOG-aldolase [67]. In the cytosol, glyoxylate can serve as substrate for both GRHPR and LDH. However, the characteristics of these enzymes and the oxidation state of their cofactors favor the preferential conversion of glyoxylate to oxalate by LDH [67].

Genetics

More than 50 *HOGA1* pathogenic variants have been detected in PH3 patients [68]. The most common variants are the c.700+5G>T splice site variant in intron 5, resulting in the in-frame insertion of 17 amino acids and the in-frame deletion c.944_946delAGG (p.Glu315del).

The estimated prevalence of PHs based on carrier frequency analysis suggests that PHs are more common than reported in clinical cohorts; this is particularly the case for PH3, which is predicted to have a similar prevalence than PH1 and to be twice as common as PH2 [4].

It has been suggested that PH3 heterozygous carriers are prone to kidney stone disease or have hyperoxaluria, but this view has recently been disputed.

Clinical Presentation

Compared to PH1 and PH2, the PH3 phenotype is less severe and is usually characterized by early-onset kidney stone disease without progression to CKD in most cases [65]. Same patients are diagnosed with a first stone episode only in their second or third decade of life. In addition, screening of sibling of patients with PH3 has identified subjects in their third decade of life with biallelic *HOGA1* pathogenic variants that have remained asymptomatic despite persistent hyperoxaluria [65, 67]. The discrepancy between the observed prevalence of the disease and the predicted prevalence from allele frequency studies confirms the milder PH3 phenotype, with many patients remaining undiagnosed.

Nephrocalcinosis is also much less common in PH3. Data from the Rare Kidney Stone Consortium PH registry indicate that nephrocalcinosis is present in 30% of PH1 patients at their first renal ultrasound examination and in 48% and 57% of patients after 10 and 20 years of follow-up, respectively. In comparison, only 7% of PH3 patients have nephrocalcinosis at their 5-year follow-up ultrasound, with no further increase at later investigations [69]. A recent analysis of the same registry has shown that stone events per decade of life was similar across the age span and the three types of PH [70].

Diagnosis

The diagnosis of PH3 should be considered in every child with kidney stone disease and in adults with recurrent CaOx stone events. Uox excretion rates are overlapping between the 3 forms of PH. It has been suggested that on average, patients with PH3 tend to have lower Uox levels, but higher urinary calcium and uric acid concentrations. Nonetheless, only 10% of PH3 patients have hypercalciuria at diagnosis [70]. The stones composition in PH3 patients is of pure CaOx monohydrate or a combination of CaOx mono- and dihydrate (weddellite) [70].

High urinary glycolic acid is characteristic of PH1 but has also been reported in PH3 patients [71]. Elevated urinary levels of HOG and of its derivative compound 4-hydroxyglutamate (4OHGlu) effectively identify patients with PH3 [67, 72]. It has been suggested that HOG is unstable at room temperature and may not represent a reliable biomarker for screening and diagnosis in this disease [72]. However, it has been used successfully in a number of laboratories. Moreover, 4OHGlu can be measured on newborn dried blood samples and may therefore be used for newborn screening [72].

The diagnosis of PH3 should always be confirmed by demonstrating pathologic variants in the *HOGA1* gene.

Treatment and Outcomes

There are no currently approved specific therapies for PH3. Conservative measures including adequate hydration and oral citrate supplements are important to increase CaOx solubility and prevent crystallization, similarly to what is recommended for PH1 (Table 2). In patients with hypercalciuria, low salt diet and thiazides are also recommended. Recommendations on dialysis and transplantation do not apply to PH3. As mentioned above, LDHA inhibition by siRNA (nedosiran) may represent an efficient and specific treatment in all types of PH. This approach is under investigation in PH3.

Some patients become asymptomatic overtime, despite persistent hyperoxaluria [73]. Only one PH3 patient progressing to ESKD has been reported to date; loss of kidney function in that patient was attributed, at least partly, to obstructive uropathy [4]. A recent analysis of the Rare Kidney Stone Consortium PH registry has shown that most PH3 patients maintain a normal GFR over time. Seven PH3 patients followed into their 40s and 50s have been reported in the registry, and only one has stage 3 CKD [70]. Three additional PH3 patients aged more than 60 years with CKD3 have also been reported. In comparison, 64% of PH1 patients and 34% of PH2 patients had reached ESKD at age 40 in the same database [70]. It has been suggested that obstructive kidney stone events in PH3 play an important role in the progression of kidney disease, but long-term follow-up studies engaging both pediatric and adult nephrologists are needed to investigate this hypothesis.

As mentioned above, some PH3 patients remain asymptomatic. The mechanisms that protect these patients from forming kidney stones despite significant hyperoxaluria are still unclear. Understanding these mechanisms may be very important to develop alternative therapeutic strategies for all patients with PH.

Secondary Hyperoxalurias

Oxalate in humans originates from the endogenous metabolism and from diet. Dietary oxalate is absorbed in the colon and distal portions of the ileum by passive diffusion and by active transport. Normal intestinal excretion of oxalates ranges 40 to 50 mg per day. The main dietary sources of oxalate include black tea, nuts, chocolate, and green leafy vegetables like spinach.

Enteric Hyperoxaluria

The principal cause of secondary hyperoxaluria is intestinal malabsorption, causing enteric hyperoxaluria. In this condition, the permeability of the colonic mucosa to oxalate is increased. In addition, fatty acids bind calcium, increasing the amount of free oxalate, which is more soluble and easily absorbed. Patients with intestinal malabsorption have a significant risk of stone disease that may cause CKD and even progress to ESKD [74]. Malabsorption disorders include inflammatory bowel diseases, chronic pancreatic insufficiency (including cystic fibrosis), ileal resection, short bowel syndrome, and celiac disease. Enteric hyperoxaluria can also be observed after bariatric surgery (mainly Roux-en-Y gastric bypass), in patients receiving unbalanced diets with restricted calcium intake, or after colon decolonization of bacteria that metabolize oxalate (lack of oxalate degrading intestinal bacteria *Oxalobacter formigenes* after wide-spectrum antibiotics, e.g., cystic fibrosis). Monitoring Uox is recommended in these conditions.

Abuse Intake of Oxalate Precursors

Excessive ascorbic acid supplements are metabolized to oxalate, which are excreted in urines. Supplements should not exceed 1000 mg per day. Vitamin C overload may represent an important issue in children on dialysis [35].

Ethylene glycol is a precursor of glycolic, glyoxylic, and oxalic acids. Poisoning with ethylene glycol may cause acute kidney and multisystemic injury, mainly in young children.

Patients with ESKD

In patients with ESKD, reliable measurement of Uox excretion is not possible [75]. Increased Pox levels up to 40 μmol/L may be observed in all forms of ESKD. Conversely, Pox concentrations above 50 μmol/L are highly suggestive of PH.

CaOx crystal deposition has been found in 4% of renal transplant biopsies [76], often because of acute tubular necrosis. Sometimes, however, these deposits are also present in the native kidneys, and in a small percentage of patients, undiagnosed PH1 or PH2 is revealed by this finding (Fig. 3). The final diagnosis requires molecular testing.

Food-Induced Secondary Hyperoxaluria

Some foods have a high oxalate concentration and can be responsible for secondary hyperoxaluria, mainly in patients with impaired GFR (star fruit, cashew nut, etc.) [77, 78].

Management

Hydration and crystallization inhibitors are as essential, similarly to patients with PH (Table 2). Specific measures are equally important, including treatment of the primary disease, dietary restriction of glyoxylate precursors, and promoting intestinal oxalate degradation with *Oxalobacter formigenes* [34, 50, 55]. Future developments include the

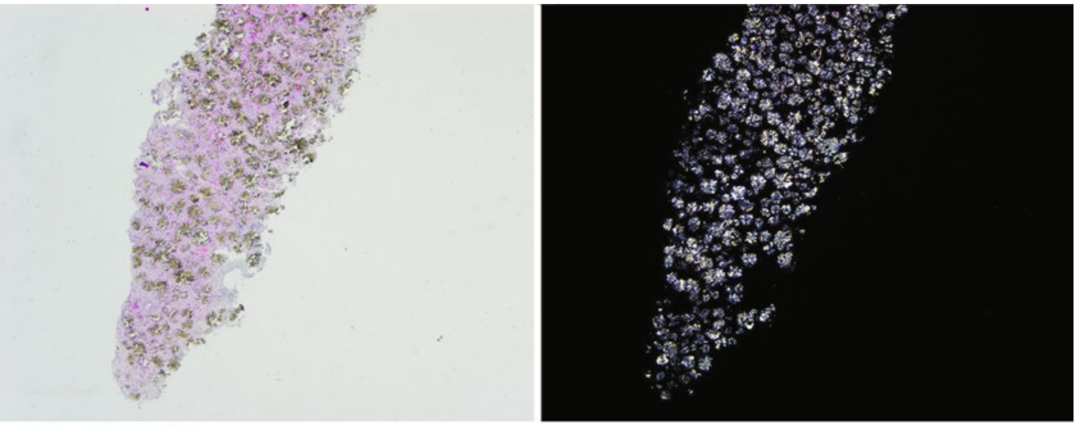

Fig. 3 Calcium oxalate deposition on bone biopsy in an adult PH1 patient with ESKD (x20) – left, hematoxylin eosin staining; right, polarized light microscopy. (Courtesy Dr N Dattner & Dr M Halfon, Lausanne, Switzerland)

use of oxalate-degrading enzymes (oxalate decarboxylase).

Conclusion

Hyperoxaluria are a group of rare heterogeneous diseases that are mostly inherited. The diagnosis should be considered in all children with a first stone episode and in adults with recurrent/bilateral nephrolithiasis, regardless of the presence of nephrocalcinosis or impaired kidney function. After excluding secondary hyperoxaluria, genotyping should be performed rapidly in order to confirm the phenotype and initiate appropriate management. Screening is recommended for all family members that are at risk, including prenatal diagnosis. Type 1 is the most common form of PH. In the past decades, most of these patients have undergone combined liver-kidney transplantation. New treatments have recently been introduced, in particular RNA interference therapies, which will most likely replace liver transplantation. Some of these treatments can also be beneficial in PH2 and PH3.

In the past years, PH has received significant attention. Guidelines for diagnosis have been produced, and new treatments have been developed. However, a large gap between high- and low-resource countries exists, which is made more relevant by the fact that the disease is most frequent, due to consanguinity, in countries with more limited medical resources. This raises unsolved ethical issues. Future efforts should focus on providing access to early screening, adequate diagnostic tools, genetic counseling, and effective therapies to patients from low-resource countries in order to avoid the need for organ transplantation, which is challenging for financial and technical reasons.

Abstract

Fanconi syndrome (FS) is generalized dysfunction of the renal proximal tubules leading to excessive urinary wasting of amino acids, glucose, phosphate, uric acid, bicarbonate, and other solutes. Patients also manifest renal salt wasting, hypokalemia, metabolic acidosis, hypercalciuria, and low-molecular-weight (LMW) proteinuria. Children with FS experience growth faltering, polyuria, polydipsia, dehydration, and rickets; adults suffer osteoporosis and osteomalacia.

De Toni, Debré, and Fanconi described children with renal rickets and glucosuria in the 1930s (De Toni, Acta Paediatr 16:479–84, 1933, Debré et al., Arch Med Enf 37:597–606, 1934, Fanconi, Jahrb Kinderheilkd 133: 257–300, 1931). FS is named after Guido Fanconi, a Swiss pediatrician, also known as "De Toni-Debré-Fanconi" syndrome.

Keywords

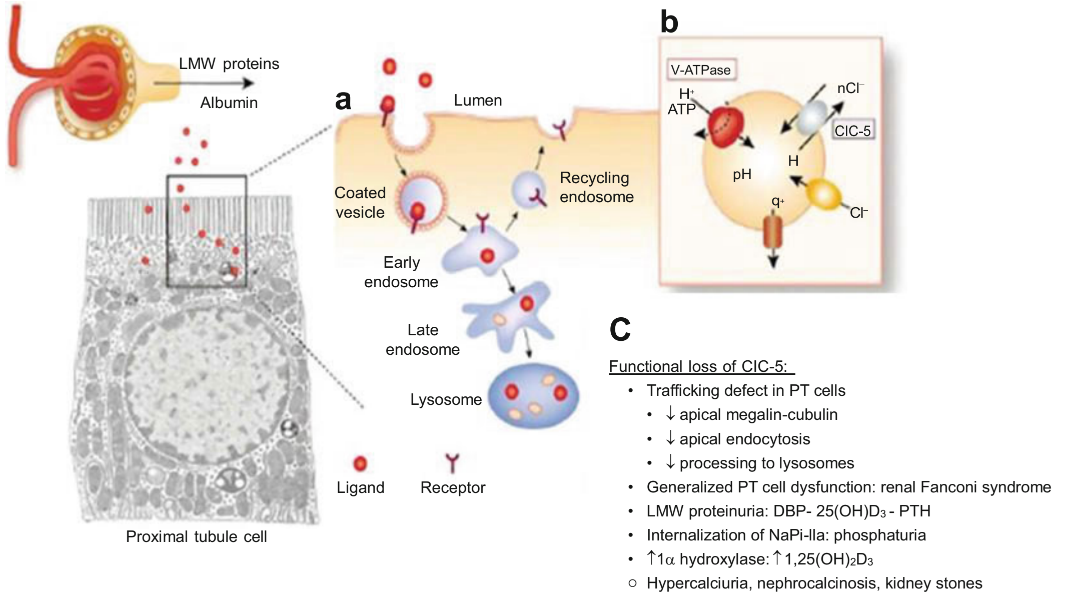
Fanconi syndrome · Generalized dysfunction of the renal proximal tubules

Pathophysiology

The renal proximal tubules reabsorb the majority of the glomerular filtrate including albumin, LMW proteins, amino acids, glucose, bicarbonate, sodium, chloride, phosphate, and uric acid. Most solute transport in the proximal tubule is mediated by receptor-mediated endocytosis or sodium gradient-dependent transport systems.

Receptor-Mediated Endocytosis

Proximal tubular cells have extensive luminal receptors and endocytic receptors such as megalin and cubam that are critical for the reabsorption, degradation, and recycling of proteins that have not been retained by the glomerular filtration barrier [1, 2] (Fig. 1). Cubam is composed of amnionless and cubilin [3]. Numerous filtered proteins including albumin, LMW proteins, polypeptide hormones, vitamin-binding proteins, and polybasic drugs such as aminoglycosides bind to megalin and cubilin in the luminal membrane of proximal tubules. The protein–receptor complex is subsequently incorporated into the endosome. The ligand and receptor are disassociated in the endosome; the receptor is recycled back to the luminal membrane and reabsorbed proteins traffic into the lysosome for further processing (Fig. 1). The disassociation of ligands from receptors is dependent on acidification of the endosome by increased concentration of H^+ and Cl^- that is mediated by the vacuolar-type H^+ -ATPase (V-ATPase) and the ClC-5 chloride channel. Disruption of the endocytic pathway compromises the recycling of megalin, cubilin, and



Functional loss of ClC-5:

- Trafficking defect in PT cells
  - ↓ apical megalin-cubulin
  - ↓ apical endocytosis
  - ↓ processing to lysosomes
- Generalized PT cell dysfunction: renal Fanconi syndrome
- LMW proteinuria: DBP- $25(OH)D_3$ - PTH
- Internalization of NaPi-IIa: phosphaturia
- ↑1α hydroxylase: ↑$1,25(OH)_2D_3$
- ○ Hypercalciuria, nephrocalcinosis, kidney stones

Fig. 1 Schematic model of endocytosis in the proximal tubule cells. Albumin and low-molecular-weight (LMW) proteins are filtered into the primary urine and endocytosed by proximal tubule cells via the megalin–cubilin receptor pathway. (**a**) The receptor–ligand complexes progress along the endocytic pathway. The endosomes undergo a progressive, ATP-dependent acidification that results in the dissociation of the receptor–ligand complexes, with megalin and cubilin being recycled in the luminal membrane, whereas the ligand is directed to lysosomes for degradation. (**b**) Vesicular acidification is mediated by the vacuolar H^+-ATPase, which requires a net Cl^- conductance to functions as an electrogenic nCl^-/H^+ exchanger, which is predicted to facilitate acidification and to play a role in keeping high vesicular Cl^- concentration. (**c**) Patients with Dent disease and ClC-5-null mice have multiple trafficking defects in PT cells, with (i) loss of megalin and cubilin in the apical brush border and their accumulation in subapical vesicles; (ii) defective apical endocytosis and low-molecular-weight proteinuria; and (iii) impaired progression toward lysosomes. These modifications result in generalized dysfunction of PT cells and renal Fanconi syndrome. As vitamin D-binding protein carries most of the circulating vitamin D in the plasma, its urinary loss may lead to bone defects and loss of $25(OH)D_3$ substrate. Increased amount of bioactive PTH in the PT lumen may interact with apical PTH receptors and stimulate internalization and degradation of the apical NaPi-IIa cotransporter, leading to phosphaturia. In turn, the phosphate loss could stimulate the 1α-hydroxylase activity in PT cells, leading to increased $1,25(OH)_2D_3$ synthesis depending on substrate availability. The balance between these effects may result in phenotype variations observed in man and mouse [4].

other transporters to the luminal membrane, causing decreased solute reabsorption. Altered endosomal acidification in proximal tubule cells decreases reabsorption and causes urinary wasting of albumin, LMW proteins, electrolytes, and solutes. For example, cadmium inhibits vacuolar acidification and mitochondrial function, which results in renal FS. Folimycin (concanamycin A), a H^+-ATPase inhibitor, abolishes albumin uptake by proximal tubules. Mutations in the ClC-5 channel in Dent disease can also cause FS [4]. In healthy children, megalin shed from proximal tubular membranes can be detected in urine. Conversely, almost no megalin is detected in the urines of patients with Dent disease, due to impaired recycling to the plasma membrane [5]. Similar results are observed in Lowe syndrome [5].

Sodium-Dependent Reabsorption

Reabsorption of filtered solutes including glucose, phosphate, amino acids, and bicarbonate by proximal tubular (PT) cells is accomplished by transport systems at the luminal brush border membrane that are directly or indirectly coupled to sodium transport. Mitochondria provide most of the energy required by the Na^+, K^+-ATPase, which maintains the electrochemical gradient allowing sodium-coupled entry of solutes into PT cells. Although kidneys make up less than 1% of total bodyweight, they consume approximately 10% of total energy in resting conditions. Transport processes consume most of the energy produced by PT cells. Usually, significant defects in PT energy production cause nonselective impairment of most transport mechanisms, resulting in FS. The mitochondrial respiratory chain has a major role in ATP production in the proximal tubule. Genetic defects that directly or indirectly alter the respiratory chain, as well as drugs and toxic substances that inhibit oxidative phosphorylation in PT cells can cause renal transport anomalies and FS [6, 7]. This is in contrast to isolated defects of apical transporter proteins resulting in selective losses of amino acids, glucose, phosphate, bicarbonate, or uric acid. Glucosuria or generalized aminoaciduria can be observed in some patients with selective apical transport defects, but these are usually modest. For example, some patients with renal glucosuria resulting from mutations in the kidney-specific low-affinity/high-capacity Na^+/glucose cotransporter gene (*SLC5A2*, 16p11.2) or with maturity-onset diabetes of the young type 3 (MODY3) caused by mutations in hepatocyte nuclear factor-1α gene (*HNF1A*, 12q24.31) that regulates transcription of *SLC5A2* [8, 9] may present with generalized aminoaciduria.

Signs and Symptoms

Growth Faltering

Growth faltering is a common feature of FS in children. Patients can present with severe growth faltering that may persist into adult life. The physiopathology of growth faltering in FS is complex. Malnutrition, hypokalemia, hypophosphatemia, and metabolic acidosis can all contribute [10].

Potassium deficiency reduces circulating levels of growth hormone (GH) and of insulin-like growth factor I (IGF-I). Hypokalemia can also decrease appetite, leading to malnutrition and extracellular volume contraction. Metabolic acidosis inhibits GH secretion and expression of IGF-I and of GH receptors [11]. Hypophosphatemia and impaired 1-alpha hydroxylation of 25-dihydroxyvitamin D lead to rickets [12]. In patients with adult-onset FS, renal phosphate wasting, and relative 1,25-dihydroxyvitamin D3 deficiency, hypophosphatemia is thought to cause osteomalacia [13]. The FS-associated metabolic acidosis also impairs 1-alpha hydroxylation. Some patients complain of bone and joint pain, and can suffer fractures. Decreased mineralization of the dentin structure and abnormal formation of craniofacial bones are also reported [14]. In forms of FS that are associated with defects in receptor-mediated endocytosis, low uptake of vitamin D and of its binding protein can aggravate metabolic bone disease [15].

Early diagnosis and treatment of acidosis and electrolyte imbalances promote growth and improve final height in children with FS. However, normal height is not often achieved, in particular in patients with cystinosis [16]. This may be related to a disease-specific bone defect.

Polyuria, Polydipsia, and Dehydration

Polyuria, polydipsia, and dehydration are frequently observed. Polyuria is primarily secondary to osmotic diuresis resulting from excessive urinary solute losses, compounded by impaired urinary concentration related to chronic hypokalemia and nephrocalcinosis. Recurrent episodes of fever due to dehydration are reported in infants [16].

Generalized Aminoaciduria

Amino acids are freely filtered by the glomerulus. Approximately 95–99% of the filtered load are reabsorbed by PT cells, which express specialized transporters in their apical and basolateral membranes. Except for histidine, which has a fractional excretion up to 5%, the fractional excretion of other amino acids is $<3\%$ in children after the neonatal period. Aminoaciduria (or hyperaminoaciduria) is therefore defined as a fractional excretion of amino acids >5%. In FS, aminoaciduria is generalized (i.e., nonselective).

$$\text{Fractional excretion of amino acid }(\%) \\ = [(\text{Uaa}/\text{Saa})/(\text{Ucr}/\text{Scr})] \times 100\%$$

(aa: amino acid; cr: creatinine; U: urine; S: serum)

Glucosuria

Glucosuria is a common manifestation in FS and is secondary to impaired reabsorption of glucose. Normally, the filtered load of glucose (D-glucose, MW = 180 D) is almost completely reabsorbed by sodium-coupled transport in the proximal tubule. Glucose reabsorption involves transporters at the luminal and basolateral membranes of the proximal tubules. Thus, a very small amount of glucose is present in the urine in health. Typically, the blood glucose level is normal. Glucosuria is one of the originally described clinical features of FS [17–19]; patients can lose 0.5–20 g/day of glucose in their urine.

Hypophosphatemia

Some patients with FS have reduced tubular reabsorption of phosphate (percent tubular reabsorption of phosphate: %TRP, >80–85% in healthy subjects) in combination with low serum phosphate concentration. Rickets and osteomalacia result from urinary phosphate wasting and impaired 1α-hydroxylation of 25-hydroxyvitamin D3 by proximal tubule cells [20]. The maximal threshold of phosphate (TmP/GFR) is a sensitive indicator of phosphate reabsorption. The Tm/GFR is usually inappropriately low in patients with FS (normal values 2.3–4.3 mg/dl). Other markers of bone chemistry such as PTH and alkaline phosphatase may be elevated in patients with FS. Serum 1,25 $(OH)_2D_3$ is variable [21].

Rickets usually manifests in small children with bowing deformity of the legs, wrist widening, and prominence of the costochondral junction, also termed “rachitic rosary.” Other signs include increased tendency for fractures, skull bossing, delayed fontanelle closure, craniotabes (soft skull), and Harrison’s groove.

$$\text{TRP }(\%) = [\,1 - (\text{Up}/\text{Sp})/(\text{Ucr}/\text{Scr})] \times 100$$

(p: phosphate; cr: creatinine; U: urine; S: serum)

$$\text{TmP}/\text{GFR} = \text{TRP} \times \text{Sp}$$

(GFR: glomerular filtration rate; p: phosphate; S: serum)

Metabolic Acidosis

More than 85% filtered bicarbonate (HCO_3^-) is reabsorbed by the PT cells, which is accomplished by the coordinated function of luminal membrane Na^+/H^+ exchanger, luminal membrane carbonic anhydrase IV and XIV, and basolateral membrane Na^+/HCO_3^- cotransporter. Defective bicarbonate reabsorption in the proximal tubules results in hyperchloremic metabolic acidosis and is a common feature of FS. The anion gap is normal. In overt forms of FS, more than 30% of the filtered load of HCO_3^- is not reabsorbed; patients have low plasma HCO_3^- levels. In patients with FS receiving alkali supplementation, fractional excretion of HCO_3^- ($FEHCO_3^-$) usually exceeds 15%. Urinary acidification in the distal tubule is usually normal, but can be sometimes impaired due to chronic hypokalemia or combined proximal-distal disease/toxicity.

Sodium and Potassium Losses

Approximately 60–80% of filtered sodium is normally reabsorbed in the proximal tubules. Sodium reabsorption is decreased in patients with FS. This may cause hypotension and dehydration. Hypokalemia is secondary to increased delivery of sodium to the distal segments and activation of the renin-angiotensin-aldosterone system as a result of hypovolemia. Potassium wasting may cause severe hypokalemia.

Hypercalciuria

Hypercalciuria is commonly observed in FS. In patients with heavy LMW proteinuria, such as in Dent disease, different mechanisms may counteract each other. Defective endocytosis of parathyroid hormone (PTH) increases its expression on the cell surface of proximal tubular cells, where it stimulates $25(OH)D_3$ 1-hydroxylase to produce more $1,25(OH)_2D_3$, raising serum levels of this vitamin. Conversely, patients lose vitamin D3-binding protein in urine, which binds $25(OH)D_3$ and presents it to the enzyme. The final levels of $1,25(OH)_2D_3$ depend on the balance of these opposing processes. Often, patients with FS have slightly elevated serum levels of $1,25(OH)_2D_3$, which increases intestinal calcium reabsorption resulting in absorptive hypercalciuria [21]. Hypercalciuria is rarely associated with nephrolithiasis in patients with FS, possibly because polyuria and alkalized urine mitigate calcium crystallization. Patients with Dent disease, however, can present with hypercalciuria and nephrolithiasis.

Hyperuricosuria

Uric acid (urate) is the end product of purine metabolism in humans. Because of its small molecular size (MW = 126 D), uric acid is freely filtered by the glomerulus. Approximately 90–95% of the filtered load of uric acid is reabsorbed in the proximal tubules. A four-component hypothesis has been proposed to explain renal uric acid transport; it includes glomerular filtration, presecretory reabsorption, secretion, and post-secretory reabsorption [22]. Hyperuricosuria is often present in FS, leading to secondary hypouricemia (<2 mg/dL). A voltage-sensitive uric acid pathway and uric acid exchangers are located at both luminal and basolateral membranes of proximal tubule cells. Uric acid reabsorption from the proximal tubule lumen into the cell is mediated by uric acid (urate)–anion exchanger (URAT1) and the glucose transporter 9 short isoform (GLUT9S) [23, 24]. *SLC2A9* produces two GLUT9 isoforms by alternative splicing; the long isoform (GLUT9L) is expressed in basolateral membrane of proximal tubular cells and the short isoform (GLUT9S) is expressed in apical membrane of proximal tubule cells [25]. The residual apical uptake of uric acid is probably mediated by OAT4 and OAT10 [26, 27]. Uric acid efflux from PT cells across the basolateral membrane appears to be primarily mediated by GLUT9L. GLUT9 was identified by screening genes associated with gout and hyperuricemia [28]. Defects in URAT1 or GLUT9 cause renal hypouricemia; patients can manifest AKI after exercise [29].

Low-Molecular-Weight Proteinuria

The PT reabsorb most proteins filtered by the glomerulus. The glomerular molecular weight cut-off for plasma proteins is approximately 65 KD (kilodaltons), similar to the molecular weight of serum albumin. A small amount of larger molecular weight proteins, including gamma globulin, can also pass the glomerular filter in normal conditions. It has been estimated that up to 9 g of albumin may be filtered every day in healthy humans [30]; of these, less than 0.1–0.15 g/day are excreted in urine.

Abnormal proteinuria can result from increased glomerular leak, defects in tubular reabsorption of proteins, or both. In FS, excess proteinuria is primarily caused by impaired reabsorption. For example, adolescent patients with FS secondary to Dent disease and Lowe syndrome excrete large amounts of proteins (1740 ± 660 mg/day) and small peptides (446 ± 145 mg/day) [31]. In patients with FS, small peptides ranging 2–5 KD are present more than 10-fold in excess, compared with normal urine [31].

Various structurally different filtered proteins, including albumin and most LMW proteins, bind to megalin and cubilin, in the luminal aspects of proximal tubules. Protein–receptor complexes are then internalized into endosomes, where they dissociate. The receptor is recycled back to the plasma membrane, while the ligand is directed towards the lysosomal compartment, where it is further processed. Megalin is a 600 KD glycoprotein that contains a large amino-terminal, an extracellular domain, a single transmembrane domain, and a short carboxy-terminal cytoplasmic tail; it is a member of the low-density lipoprotein receptor family. Megalin is expressed in the proximal tubule brush border and luminal endocytic apparatus. Cubilin is a 460 KD multiligand endocytic receptor with little structural homology to other known proteins. It is expressed in the proximal tubule brush border and luminal endocytic apparatus. Megalin has a primary role in reabsorbing filtered albumin both directly, as a receptor for albumin, and indirectly by promoting the expression of cubilin [32]. Patients with Dent disease have decreased expression of megalin. The acidification defect secondary to impaired chloride conductance alters recycling of megalin and cubilin from the endosomal compartment to the plasma membrane.

Decreased Urinary Excretion of Osteopontin and Uromodulin

Osteopontin is excreted into the urine from renal tubule cells. It plays a role in remodeling of extracellular matrix and inhibition of apoptosis, and as a protective factor against nephrocalcinosis. Uromodulin (Tamm-Horsfall protein) is also excreted by renal tubule cells and plays a role in combating urinary tract infections. Proteome analysis revealed that urinary excretion of both proteins is reduced in patients with FS [33].

Causes of FS

Causes of FS can be divided into hereditary, acquired, and exogenous toxins (Table 1). Most hereditary FS occurs in the context of congenital inborn errors of the metabolism or, more rarely, as sporadic or familial disorders. Acquired forms are mostly secondary to immunological disorders, nephrotic syndrome, or accumulation of abnormal proteins in renal tubules. Exogenous substances include drugs, chemical compounds, and heavy metals.

Table 1 Causes of Fanconi syndrome

Hereditary
Dent disease
Lowe syndrome
Mitochondriopathies
Enoyl-coenzyme A hydratase/L-3-hydroxyacyl-coenzyme A dehydrogenase
EHHADH deficiency
Cystinosis
Galactosemia
Hereditary fructose intolerance
Glycogen storage disease type 1 (von Gierke disease)
Fanconi-Bickel syndrome
Tyrosinemia type I
Wilson disease
Lysinuric protein intolerance
Microvillus inclusion disease
Maturity-onset diabetes mellitus of the young (MODY)
Type IIa sodium/phosphate cotransporter (NaPi-IIa) deficiency
Arthrogryposis-renal dysfunction-cholestasis (ARC) syndrome
Idiopathic
Acquired
Nephrotic syndrome
Myeloma
Sjögren syndrome
Renal transplantation
Acute tubulointerstitial nephritis and uveitis (TINU) syndrome
Autoimmune interstitial nephritis and membranous nephropathy
Anorexia nervosa
Untreated condition of distal renal tubular acidosis
Exogenous substances
Drugs
Chemical compounds
Heavy metals

Hereditary Causes of Fanconi Syndrome

Cystinosis

See ▶ Chap. 37, "Cystinosis"

Dent Disease

Dent disease is an X-linked proximal tubulopathy characterized by LMW proteinuria, hypercalciuria, nephrocalcinosis, and progression towards end-stage kidney disease. Hypophosphatemic rickets, hypokalemia, metabolic acidosis, and nephrolithiasis (calcium oxalate and/or phosphate) are often observed [34, 35]. Almost all patients are males. Most adult patients have FS. Children manifest with LMW proteinuria and usually one or two additional signs of PT dysfunction (partial FS) [36]. Extrarenal symptoms are rare, with the exception of rickets. In Japan, a school screening program identified asymptomatic children with Dent disease [37].

Dent disease is genetically heterogeneous. In approximately 60% patients, Dent disease is caused by inactivating mutations of the *CLCN5* gene (Xp11.23), which encodes for a 746 amino acid chloride channel [38]. ClC-5 is exclusively expressed in the kidney. The disease is termed more specifically Dent disease 1 (DD1), to differentiate it from similar phenotypes caused by *OCRL1* mutations [see below, Dent disease 2 (DD2)]. ClC-5 belongs to the family of voltage-dependent chloride channels, which function as homodimeric proteins. It is co-expressed with the V-ATPase and plays a key role in the endosomal acidification process, which is a critical step in the receptor-mediated endocytic pathway [39]. There is no clear genotype–phenotype correlation; a large degree of variation in phenotype is observed between affected members of the same family [37]. Carrier females have significantly less severe LMW proteinuria and hypercalciuria; some with unfavorable X-chromosome inactivation may develop clinically significant symptoms.

Abnormal endocytosis secondary to *CLCN5* mutations disturbs normal recycling of megalin and cubilin to the luminal membrane, causing LMW proteinuria, and alters the expression of other transporter proteins, causing partial or complete FS. LMW proteins undergo receptor-mediated endocytosis in proximal tubules (see above). Chloride-influx via ClC-5 facilitates endosomal acidification by maintaining electroneutrality of ion transport. The absence or dysfunction of ClC-5 disrupts endosome recycling in the PT cells by reducing receptor internalization, altering progression of endosomes to lysosomes and disrupting recycling of endosomes to the cell surface [40].

In most cases, excess proteinuria ranges from 0.5 to 2.5 g per day but may exceed 4 g in some patients. Proteins with a molecular weight <45 KD represent approximately 60% of the filtered protein load. LMW proteinuria is a consistent feature of Dent disease in all patients. Markers of LMW proteinuria, such as β2-microglobulin (MW = 11.6 KD), are excreted in the urine in amounts reaching 100–300 times the upper limit of the normal value. Excess albumin (MW = 65 KD) is also lost in urine, but not in quantities causing hypoalbuminemia and nephrotic syndrome. This pattern of proteinuria with predominant excretion of excess LMW proteins is termed tubular proteinuria and has been used interchangeably with “LMW proteinuria.”

Impaired urinary concentrating ability is frequently observed. Reduced expression of sodium hydrogen exchanger 3 (NHE3) in PT cells may also contribute to polyuria by increasing sodium losses.

The pathophysiology of hypercalciuria is complex. Overall, 70% of patients with *CLCN5* mutations have hypercalciuria. Nephrocalcinosis is a frequent finding (Fig. 2), but it is not present in all patients. Urinary calcium excretion is usually in the range of 4–10 mg/kg/day in affected children and 4–6 mg/kg/day in adults [41]. Vitamin D metabolism is subject to opposing effects resulting from decreased recycling of the PTH receptor to the luminal membrane of PT cells, and increased urinary losses of vitamin D-binding protein. Slightly elevated serum levels of $1,25\text{-}(OH)_2D_3$ are often observed in patients with Dent disease and can lead to increased intestinal Ca^{2+} reabsorption and hypercalciuria. Expression of ClC-5 in other nephron segments may also play an important role in the pathophysiology of hypercalciuria. In vitro, inactivation of the *CLCN5* gene in collecting duct cells promotes membrane retention of annexin 2, which facilitates formation of calcium-based crystals on the cell surface and may explain the nephrocalcinosis observed in many patients [42]. Decreased urinary excretion of osteopontin, a protective factor against nephrocalcinosis, can also play a role. Nephrolithiasis occurs in about 25% patients.

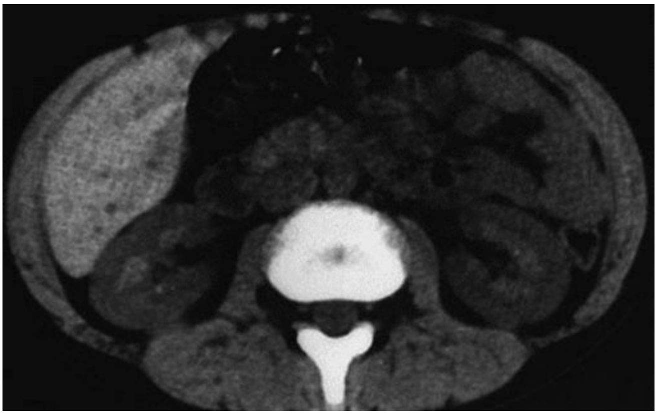


Fig. 2 Abdominal CT demonstrating bilateral medullary nephrocalcinosis in a 12-year-old boy with Dent disease

Hypophosphatemia secondary to renal phosphate losses is observed in almost half of adult patients with DD1. Phosphate is reabsorbed in the proximal tubules by the NaPi-IIa and NaPi-IIc proteins (type IIa and IIc sodium/phosphate cotransporters). In ClC-5 knockout mice, altered apical endocytosis of filtered PTH decreases apical expression of NaPi2a, leading to urinary phosphate wasting [43].

In the collecting duct, ClC-5 colocalizes with V-ATPase in apical and subapical vesicles. Decreased ClC-5 function probably disturb recycling of these vesicles leading to defective apical expression of the V-ATPase in collecting ducts and impaired urinary acidification.

Kidney function in patients with Dent disease is highly variable. Some progress to end-stage kidney disease, typically in the fifth to sixth decades of life; one-third of patients do not progress to end-stage kidney disease; some develop significantly impaired kidney function in childhood. Kidney biopsy has no diagnostic role. Histology shows normal or focal global glomerulosclerosis with tubular atrophy, tubular dilatation, and interstitial infiltration of inflammatory cells. The underlying mechanisms leading to end-stage kidney disease in DD1 are incompletely understood. Medullary nephrocalcinosis may contribute. High urinary concentrations of bioactive proteins including insulin, insulin-like growth factor-1 (IGF-1), and the chemokine monocyte chemoattractant protein-1 (MCP-1) may contribute to interstitial fibrosis. Proximal tubule dysfunction is associated with cell dedifferentiation and oxidative stress.

Pathogenic variants in the *OCRL1* gene (Xq26.1) have been identified in approximately 15% of patients with a Dent phenotype [44]. This phenotype is referred to as Dent disease 2 (DD2). Approximately 25% of the patients with Dent disease remain genetically unresolved. Pathogenic variants in *OCRL1* usually cause Lowe syndrome; unlike patients with typical Lowe syndrome, patients with DD2 have normal or near normal facial appearance, intelligence, muscle tone, and ocular findings. Their phosphoinositol 4,5-bisphosphate phosphatase (PIP_2 5-phosphatase) activity is markedly reduced in skin fibroblasts and protein expression is reduced or absent. This enzyme regulates endosomal trafficking and recycling, causing LMW proteinuria if mutated (see below). Unlike patients with Lowe syndrome, patients with DD2 usually do not develop metabolic acidosis. Similarly to Lowe syndrome, however, their lactate dehydrogenase (LDH) and creatinine phosphokinase (CPK) levels are frequently increased, a sign that may orient the initial genetic testing. Also, glycosuria is very rarely reported with OCRL1 variants. Phenotypic differences between DD2 and Lowe syndrome are not explained by the severity of OCRL1 variants. However, nearly all variants associated with Lowe syndrome are located in exons 8–23, whereas the majority of pathogenic variants for DD2 are located in exons 1–7 and those that are located after exon 7 are always missense mutations [146].

There is currently no specific treatment to protect kidney function in Dent disease. Thiazides have been administered to mitigate hypercalciuria, aiming to preserve kidney function

[45, 46]. However, no long-term study has provided evidence that this treatment delays the natural history of progression. Moreover, patients developed adverse reactions, including muscle cramps, hypovolemia, hypokalemia, and hyponatremia [46]. A high citrate diet delayed progression of nephrocalcinosis and of chronic kidney disease in *clcn5* knockout mice [47]. Treatment with angiotensin-converting enzyme (ACE) inhibitors or angiotensin receptor blockers (ARB) may also delay progression [48]; however, these treatments should be used with caution in patients with urinary concentration defects. Animal data in a mouse model of Dent disease suggested that bone marrow transplantation could rescue the epithelial phenotype of the proximal tubules [49].

Lowe Syndrome

Lowe oculocerebrorenal syndrome is a rare X-linked disorder caused by variants in the OCRL1 gene (Xq26.1). The syndrome is characterized by a complex phenotype that includes severe eye abnormalities, central nervous system abnormalities, and FS [50, 163].

Cataracts are recognized in all male patients. Lens opacities are present in all carriers of females by slit-lamp examination and has been used to screen for carriers [51]. Other ocular abnormalities include glaucoma, microphthalmos, and corneal keloid formation. Visual acuity is disturbed. Central nervous system abnormalities include infantile hypotonia (floppy infant), areflexia, and developmental delay. Ventriculomegaly and periventricular cysts may be seen. Some patients experience seizures including status epilepticus. FS is a major clinical feature and commonly occurs in the first year of life, but the severity and age of onset vary. All patients manifest LMW proteinuria. Aminoaciduria, hyperphosphaturia, hypercalciuria, hypophosphatemic rickets, hyperchloremic metabolic acidosis are frequently reported, while glucosuria is rare [61, 147]. All patients develop progressive renal insufficiency and typically progress to end-stage kidney disease by the 30s or 40s [52]. Compared to patients with DD2, patients with Lowe syndrome demonstrate faster decline in kidney function [147].

Megalin is nearly absent from urine in patients with Lowe syndrome, indicating decreased megalin expression in the luminal membrane of the proximal tubule cells, while *N*-acetylglucosaminidase is significantly increased, indicating urinary shedding of lysosomes [53].

The *OCRL1* gene (Xq26.1) encodes an inositol polyphosphate 5-phosphatase [54, 146]. This enzyme is a predominantly lipid phosphatase that regulates cell levels of phosphatidylinositol 4,5-bisphosphate, which is a critical metabolite of the inositol phosphatase signaling pathway [55, 146]. It is expressed in skin fibroblasts, but not present in peripheral blood cells. Its activity is markedly reduced in fibroblasts from patients with Lowe syndrome [56], but the test cannot reliably detect female carriers.

Deficiency of inositol polyphosphate 5-phosphatase OCRL leads to cellular accumulation of its substrate PIP2 (Phosphatidylinositol (4,5)-bisphosphate) [57]. PIP2 is involved in signal transduction, vesicle trafficking, and actin polymerization. Absence of PIP2 5-phosphatase activity impairs actin metabolism, altering several epithelial functions, including cell–cell interactions, clathrin-mediated endocytosis, trafficking of receptors through early endosomes, recycling of proteins to the plasma membrane, retrograde transfer to the Golgi complex, and sorting of cargo to lysosomes [58, 59, 146]. In addition, PIP2 accumulates in autolysosomes causing defective autophagic flux [146]. Lack of OCRL causes abnormal morphology of the primary cilium in several cells types [146]. Finally, *OCRL1* has a C-terminal RhoGAP domain that binds the Rac GTPase. Altered Rho-dependent pathways may play an important role in developmental delay in Lowe syndrome, as observed in other forms of X-linked developmental syndromes [60].

Many *OCRL1* variants have been described in patients with Lowe syndrome; nearly all are clustered in exons 10–23, especially exon 15, and almost none are found in exons 1–9 [56, 147].

Treatment is supportive and includes care of ocular manifestations and dental complications, seizures, and speech therapy. Cataracts should be treated early. Usually patients require supplementation with bicarbonate, sodium, or potassium phosphate, and vitamin D; requirements vary significantly from patient to patient.

Life expectancy is reduced in patients with Lowe syndrome to approximately 30–40 years. End-stage kidney disease is the most frequent cause of death. Some patients have been treated with dialysis, but behavioral instability, in particular aggressive behavior, often represents an important hurdle to successful kidney replacement therapy. A minority of patients have undergone kidney transplantation.

Mitochondrial Diseases

Since PT cells are metabolically very active and dependent heavily mitochondria for their energy supply, many mitochondrial cytopathies can cause FS [153] (see ▶ Chap. 33, "The Kidney in Mitochondrial Diseases").

Most patients with FS secondary to mitochondrial cytopathies present with complete FS, usually before the age of 2 years, in combination with extrarenal symptoms, mostly neuromuscular. In some cases, the FS is incomplete. Kidney biopsy, if performed, often shows cytoplasmic vacuolization of tubular cells with tubular dilatation and atrophy. Abnormal mitochondria are frequently observed by electron microscopy.

Treatment of the FS is mainly symptom-based and includes supplementing sodium bicarbonate, potassium, vitamin D3, phosphate, and fluid as needed. Drugs that interfere with the respiratory chain, such as valproate and barbiturates, or that inhibit mitochondrial protein synthesis, such as tetracyclines and chloramphenicol, should be avoided.

Enoyl-Coenzyme A Hydratase/L-3-Hydroxyacyl-Coenzyme A Dehydrogenase (EHHADH) Deficiency

Some variants in the *EHHADH* gene (3q27.2), which encode EHHADH (enoyl-coenzyme A hydratase/L-3-hydroxyacyl-coenzyme A dehydrogenase), can lead to FS. Patients present with rickets, impaired growth, glucosuria, generalized aminoaciduria, phosphaturia, metabolic acidosis, and LMW proteinuria [62].

EHHAD is a peroxisomal protein involved in β-oxidation of fatty acids. Variants at p.E3K result in a de novo mitochondrial import sequence, resulting in mistargeting to mitochondria. The mutated EHHADH protein is incorporated into mitochondrial trifunctional protein, thereby disturbing β-oxidation of long-chain fatty acid and mitochondrial energy production, which is predominantly based on fatty acid oxidation (FAO) in proximal tubular cells, leading to FS [63].

Galactosemia

Galactosemia is an autosomal recessive disorder affecting galactose metabolism. In nursing infants, large amounts of galactose are processed through the Leloir pathway in order to utilize carbon for energy [64]. Classic galactosemia is due to deficient activity of galactose-1-phosphate uridyltransferase (GALT) enzyme encoded by the *GALT* gene (9q13.3) [65]. GALT catalyzes the metabolism of galactose-1-phosphate (gal-1-p) plus uridine diphosphate glucose to uridine diphosphate galactose plus glucose-1-phosphate (Fig. 3). Uridine diphosphate galactose can be further metabolized to either glucose or CO_2 and H_2O via glycolysis. Milk is a major source of galactose. Accumulated gal-1-p due to defective GALT and exposure to galactose leads to acute metabolic deterioration in multiple organ systems, including liver, kidney, ovary, brain, and eye. GALT deficiency results in accumulation of toxic amount of galactose leading to unfolding of proteins, altered calcium homeostasis, and endoplasmic reticulum (ER) stress [66]. ER stress caused by GALT deficiency may contribute to accelerated apoptosis of follicular cells, leading to premature ovarian failure in females [67]. Abnormal synthesis of galactitol from galactose through aldose reductase probably represents a key element in the pathophysiology of cell

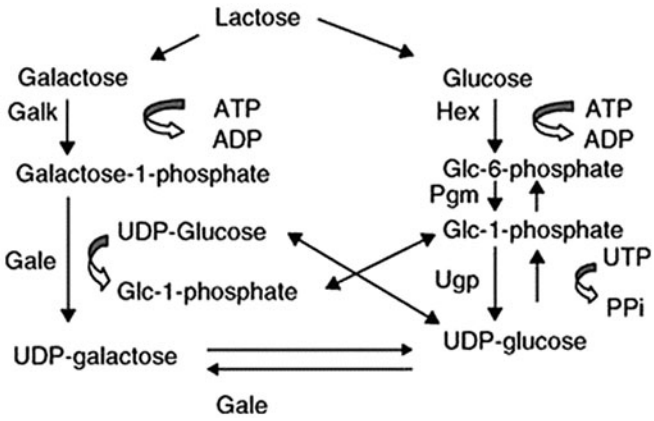

Fig. 3 Composite diagram of the Leloir pathway and uridine diphosphate (*UDP*)–glucose pyrophosphorylase pathway. *Galk* galactokinase, *galt* galactose-1-phosphate uridyltransferase, *Gale* UDP-galactose 4-epimerase, *Hex* hexokinase, *Pgm* phosphoglucomutase, *Ugp* UDP-glucose pyrophosphorylase [64]

damage in galactosemia and is responsible for the formation of cataracts.

Affected infants manifest vomiting, diarrhea, growth faltering, developmental delay, liver dysfunction, coagulopathy, renal tubular dysfunction, cerebral edema, vitreous hemorrhage, and sepsis (mostly *Escherichia coli*). They sometimes develop jaundice with unconjugated hyperbilirubinemia and may suffer from severe hemolysis. Liver damage leads to hepatomegaly and cirrhosis that can be lethal. Thanks to neonatal screening programs [71], most patients are diagnosed very early, which allows minimizing long-term complications, such as developmental delay. Patients placed on a galactose-restricted diet, however, are never truly free of galactose, as a significant amount is found in nondairy foodstuffs such as vegetables and fruits [68]. More importantly, galactose moieties can also be produced endogenously from UDP-glucose via the UDP-4-galactose epimerase reaction during the natural turnover of glycoproteins and glycolipids [69]. Therefore, even well-treated patients can develop debilitating complications [70]. Growth retardation, speech delay, and cerebellar symptoms are common. Premature ovarian failure nearly always develops in females. The most frequent renal finding is FS.

Treatment involves elimination of galactose from the diet. Acute symptoms and signs resolve within a few days of starting dietary restriction.

Hereditary Fructose Intolerance

Hereditary fructose intolerance (HFI) is an autosomal recessive disorder caused by a deficiency in the liver, the intestine, and renal cortex of aldolase B (fructose-1-phosphate aldolase), which catalyzes breakdown of exogenous fructose [72]. The frequency of HFI is estimated at 1 in 20,000 live births. Aldolase B is encoded in *ALDOB* gene (9q31.1) [73]. It cleaves fructose-1,6-bisphosphate (FBP) and fructose-1-phosphate (F1P) into dihydroxyacetone phosphate and D-glyceraldehyde-3-phosphate, or into dihydroxyacetone phosphate and D-glyceraldehyde, respectively.

Shortly after the intake of fructose or related sugars, including sucrose and sorbitol, affected individuals manifest symptomatic hypoglycemia, vomiting, restlessness, which can progress to life-threatening shock [74]. Protracted ingestion of fructose causes growth faltering, hepatomegaly, jaundice, hepatic cirrhosis, and nephrocalcinosis, and may lead to convulsions, coma, and death from severe liver and kidney failure. Symptoms of HFI appear during infancy when infants start solid food including fruit, vegetables, and sweetened foods that contain sucrose. Current formulae are no longer sweetened with fructose or sucrose. Patients with HFI often develop aversion to sweets and fruits.

At the renal level, HFI causes PT dysfunction leading to aminoaciduria, bicarbonaturia, and phosphaturia. These changes occur rapidly after ingestion of fructose [72, 74]. Development of lactic acidosis adds significantly to the metabolic acidosis [75]. Chronic fructose ingestion leads to nephrocalcinosis and impaired distal tubular function. In contrast, resolution of proximal tubule dysfunction occurs within days or weeks after strict dietary restriction of fructose and sucrose.

Aldolase B is abundantly co-expressed in endocytic structures of the PT cells, together with H^+-ATPase [76]. The pathophysiology of FS in HFI is not clearly understood but may involve, at least in part, defective endosomal acidification.

The diagnosis is confirmed by molecular genetic testing, which has largely replaced previous biochemical investigations. Strict avoidance of foods and drugs containing fructose, sucrose, and sorbitol is the mainstay of treatment.

Glycogen Storage Disease Type I

Glycogen storage disease type I (GSD-I, von Gierke disease) refers to a group of autosomal recessive disorders with an incidence of 1 in 100,000. There are two major subtypes [151, 152]. Glycogen storage disease type Ia (GSD-Ia) is common (80%) and is caused by the mutation in *G6PC* gene (17q21.3) resulting in the deficiency of glucose-6-phosphatase-alpha (G6Pase-alpha), a key enzyme in glucose homeostasis that catalyzes the hydrolysis of glucose-6-phosphate (G6P) to glucose and phosphate in the terminal step of gluconeogenesis and glycogenolysis [77]. Glycogen storage disease type Ib (GSD-Ib) is caused by the mutation in *SLC37A4* gene (11q23.3) resulting in the deficiency of microsomal glucose-6-phosphatase transporter (G6PT). G6PT and G6Pase-alpha work in concert to maintain glucose homeostasis. Whereas G6Pase is exclusively expressed in gluconeogenic cells, G6PT is ubiquitously expressed and its deficiency generally causes a more severe phenotype.

Patients with GSD-Ia manifest a phenotype of disturbed glucose homeostasis characterized by life-threatening hypoglycemia, hepatomegaly, nephromegaly, hypercholesterolemia, hypertriglyceridemia, hyperuricemia, lactic acidemia, and growth retardation. Infants with GSD-Ib typically present with seizures and hepatomegaly around 6–8 months of age. Approximately 75% of adolescents and adults develop liver adenoma [78].

Renal symptoms and complications include nephromegaly, gout nephropathy, renal stones, nephrocalcinosis, FS, and chronic kidney disease [79]. Hyperuricemia and uric acid stones are caused by a combination of increased synthesis of purine and competitive inhibition of renal tubular excretion of uric acid by lactate [80]. Patients develop proximal renal tubular acidosis, hyperphosphaturia, generalized aminoaciduria, and increased excretion of LMW proteins. Renal biopsies in patients show interstitial fibrosis, tubular atrophy, and focal segmental glomerulosclerosis, with glomerular enlargement and thickening and lamellation of the glomerular basement membrane (GBM) [82]. Glycogen depositions are present in both tubular and glomerular cells.

Diagnosis is made by molecular genetic testing of *G6PC* and *SLC37A4*. Genetic testing has largely replaced traditional liver biopsy to measure enzyme activity (G6Pase catalytic activity and G6P exchanger SLC37A4 activity). Nonetheless, liver biopsy may still be useful in selected cases to investigate liver pathology and to test variants of uncertain significance.

Treatment is aimed at maintaining normoglycemia to avoid metabolic complications and lactic acidosis. Small frequent meals and snacks with high complex carbohydrate content are the mainstay of treatment [83]. During infancy, normoglycemia is accomplished at night with nasogastric tube feeding of glucose or with orally administered uncooked cornstarch. Recommended uncooked cornstarch doses are 1.6 g/kg body weight every 4 h for infants, 1.7–2.5 g/kg body weight every 6 h for young children through puberty, and 1.7–2.5 g/kg body weight given before bedtime for adults [84].

Progression of renal disease is markedly improved by strict adherence to diet [80, 81, 148, 149]. Tubular function abnormalities can also partially recover in very compliant patients [81]. ACE inhibitors have a demonstrated renoprotective effect in GSD-Ia [149, 150] and lipid-lowering agents may be beneficial. However, despite optimal treatment, glomerular hyperfiltration develops over time in most patients, and some progress to end-stage kidney disease [83, 148]. Liver transplantation is indicated in patients when medical treatment fails to achieve metabolic control, or when liver adenoma or hepatocellular carcinoma develop. Isolated or combined kidney and/or liver transplantation have been successfully performed [151, 152]. Living-donor liver transplantation is a viable option to restore normal metabolic balance and preserve kidney function [85, 152]. Hepatocyte transplantation is also used to prevent hypoglycemia and allow discontinuation of cornstarch meals [154].

Fanconi–Bickel Syndrome

Fanconi–Bickel syndrome (FBS) is an autosomal recessive disorder of monosaccharide transport, usually presenting in the first year of life with characteristic "doll-like" facies, hepatomegaly, nephromegaly, and severe FS causing rickets [86]. Patients with FBS accumulate glycogen in hepatocytes and proximal tubule cells, and develop hypoglycemia and galactose intolerance [89]. Some are diagnosed with early onset cataract [87]. The overall prognosis of FBS is usually favorable, but cases of fatal liver failure during infancy have been reported [88, 89].

The disease is caused by variants in the *SLC2A2* gene (3q26.2), encoding the GLUT2 facilitative glucose transporter, which is expressed in hepatocytes, pancreatic beta cells, and in the basolateral membranes of intestinal and renal tubular epithelial cells [156]. The inability of the liver to transport glucose, together with heavy renal losses of glucose, cause preprandial hypoglycemia [89]. Rarely, decreased monosaccharide uptake by the liver can cause postprandial hyperglycemia and hypergalactosemia, which is exacerbated by inappropriately low insulin secretion due to abnormal glucose-sensing by pancreatic beta cells. Hyperglycemia and glycosuria are sometimes the first signs of the disease in the neonatal period [158]. Renal glomerular hyperfiltration, microalbuminuria, and diffuse mesangial expansion have been reported in one child [90].

Disease severity is variable with no genotype phenotype correlation [156]. Some patients are misdiagnosed as having autosomal recessive or idiopathic FS. Compared to other forms of FS, patients with FBS have particularly severe glucosuria and galactosuria. The diagnosis is confirmed by molecular genetic analysis of *SLC2A2*.

Treatment is symptomatic and includes frequent meals and management of the FS [89]. This usually requires vitamin D3 and oral phosphate, and, depending on to the severity of the proximal tubulopathy, alkali, and salt supplementation. Frequent feeds, including at night, help prevent hypoglycemia and ketosis. Uncooked cornstarch and nocturnal enteral nutrition have been shown to decrease the frequency of hypoglycemic episodes and improve growth [91, 157]. Patients should eat fructose as their main source of carbohydrates and should avoid galactose to limit accumulation of glycogen in the liver and in kidneys.

Tyrosinemia Type I

Hereditary tyrosinemia type I (HTI) is an autosomal recessive disorder characterized by elevated blood levels of tyrosine. HTI is caused by mutations in the *FAH* gene (15q25.1), which encodes for the fumarylacetoacetate hydrolase (FAH) enzyme that converts fumarylacetoacetate into acetoacetate and fumarate [159, 160]. If mutated, L-tyrosine metabolism is impaired, and fumarylacetoacetate accumulates and is converted primarily into succinylacetone (Fig. 4) [159]. Succinylacetone is a toxic metabolite that causes FS by inhibiting brush border transporters, altering plasma membrane fluidity, and impairing oxygen consumption [163]. Inactivation of the L-tyrosine pathway upstream of the fumarylacetoacetate hydrolase reaction causes accumulation of tyrosine without significant renal disease [164], whereas direct

Fig. 4 Panel A illustrates the metabolic pathway of tyrosine metabolism. Tyrosinemia type I is caused by pathogenic variants in the FAH gene that encodes the fumarylacetoacetase enzyme (FAA). Loss of function of FAA leads to accumulation of succinylacetone that causes proximal tubular dysfunction. Nitisinone (NTBC) inhibits the tyrosine pathway upstream of the FAA reaction, preventing synthesis of succinylacetone. Panel B shows severe rickets in a 3-year-old patient with tyrosinemia type I. Panel C shows the abdominal CT-scan of the same patient, demonstrating diffused nodular changes of the liver parenchyma [161]

injection of succinylacetone in rats causes proximal tubular damage [165]. In humans, the FS improves after succinylacetone levels decrease following liver transplantation [95, 165].

Most patients present in early infancy with acute liver failure [160]. A more subacute clinical presentation occurs between the ages of 6 and 24 months, and is characterized by failure to thrive, hepatosplenomegaly, coagulopathy, FS, and progressive neurological symptoms [160]. These include painful peripheral neuropathy that can lead to transient paralysis, and autonomic dysfunction that is often complicated with hypertension and tachycardia. Rarely, patients develop a more chronic form of the disease and are diagnosed after the age of 2 years with subclinical hepatic and renal tubular dysfunction [160]. Patients with HTI are at high risk of developing hepatocellular carcinoma [92]. In addition to tyrosine, they have elevated plasma concentrations of methionine, phenylalanine, and aminolevulinic acid, and excrete high concentrations of tyrosine metabolites in their urine [160]. Liver function tests are usually normal or moderately elevated. Alpha-fetoprotein is markedly increased, in particular in patients with hepatocellular carcinoma.

The FS of HTI is typically associated with hypophosphatemic rickets (Fig. 4). Generalized aminoaciduria, renal tubular acidosis, and LMW proteinuria are often present, whereas glucosuria is less common. Kidneys are often enlarged, and nephrocalcinosis is occasionally observed.

Glomerulosclerosis and chronic kidney disease develop progressively in untreated patients (Fig. 5).

The diagnosis of HTI is usually made by newborn screening, using tandem mass spectrometry to detect succinylacetone [93, 160], and is confirmed by molecular testing. Treatment should be started as soon as possible. It includes dietary restriction of tyrosine and phenylalanine, along with nitisinone (2-[2-nitro-4-trifluoromethylbenzoyl]-1,3-cyclohexanedione – NTBC) to block the tyrosine pathway upstream of the fumarylacetoacetate hydrolase reaction, preventing accumulation of succinylacetone and other potentially toxic metabolites [94]. FS improves significantly with NTBC treatment [161], and after liver transplantation [95, 165]. However, in some patients, liver transplantation alone cannot abolish urinary succinylacetone excretion and renal disease may still progress [165].

Wilson Disease

Wilson disease is an autosomal recessive inborn error of copper (Cu) metabolism with an estimated frequency of 1:30,000 [166]. The disease is caused by pathogenic variants in the *ATP7B* gene (13q14.3) that encodes for the Cu-transporting ATPase 2 [96].

Copper is present in excess in the diet; therefore, its levels in the body are primarily regulated by biliary excretion. Copper homeostasis in cells and tissues is maintained by a number of proteins including transporters, storage molecules (metallothioneins), cytosolic carriers, and enzymes that use Cu as a co-factor [166]. After intestinal absorption, Cu is released into the circulation and reaches the liver tagged with albumin. In the liver, Cu-transporting ATPase 2 promotes biliary Cu excretion (Fig. 5). In addition, it mediates

incorporation of Cu into apoceruloplasmin, the precursor of ceruloplasmin. Ceruloplasmin carries 90% of circulating Cu and transfers Cu to peripheral tissues [167]. Mutations in the *ATP7B* gene cause decreased conversion of apoceruloplasmin into ceruloplasmin, which is often low in patients with Wilson disease. As a result, Cu circulates loosely bound to albumin and other proteins, and is continuously up taken by tissues. Most clinical symptoms of Wilson disease are directly related to Cu toxicity. Decreased biliary excretion further increases Cu accumulation and toxicity in hepatocytes. Copper excess induces oxidative stress that causes damage to lipids, proteins, and nucleic acids [166]. It also induces apoptosis and inhibits the activity of several enzymes [166]. Mitochondria, in which PT cells are particularly reach, are very sensitive to Cu-induced toxicity [166]. More than 700 different pathogenic variants in *ATP7B* have been reported. The R778L variant is very frequent in south-east Asia, the H1069Q variant is predominant in patients of central, eastern, and norther European ancestry, while other genetic changes are typical in southern Europe [166]. Phenotype-genotype correlations have been evaluated in numerous studies with no consistent findings.

Patients with Wilson disease develop neurological and liver lesions over time. Symptoms rarely manifest before 6 years of age. Hepatic signs are present at onset in 40–60% of subjects. Most frequently, patients develop progressive hepatic steatosis, which can be diagnosed by ultrasonography or liver biopsy. Liver function tests are mildly elevated and, if left untreated, liver disease progresses to cirrhosis [166]. In other cases, patients present with acute liver failure, in particular young females [166]. Neurological symptoms are the second most frequent presenting symptoms and are reported in 20–60% of patients [167]. They are heterogeneous, but include movement disorders, such as tremors, involuntary movements, dystonia, dysarthria, Parkinsonism, or dysphagia; less frequently, patients develop seizures [97]. Approximately 20% of patients have neuropsychiatric manifestations at diagnosis. Other presenting features include hemolytic anemia, bone fractures, arrhythmias, FS, skin hyperpigmentation, sunflower cataract, and the characteristic Kayser-Fleischer ring. This latter feature is caused by Cu accumulation in the cornea, and is observed in 20–30% of asymptomatic patients, 40–50% of patients with liver disease, and nearly all patients with overt neurological symptoms [166]. Menstrual irregularities, delayed puberty, gynecomastia, and miscarriage are also frequent.

In the kidney, accumulation of Cu causes tubular dysfunction. Patients can develop FS before overt hepatic disease, including intermittent glucosuria, aminoaciduria, hyperphosphaturia, hyperuricosuria, or LMW proteinuria [98]. Other urinary findings include hypercalciuria, urolithiasis, nephrocalcinosis, decreased urine concentrating ability, and distal renal tubular acidosis. Kidney function progressively deteriorates in untreated patients, but usually death occurs from nonrenal causes before the onset of end-stage kidney disease.

The diagnosis of WS is based on a combination of clinical and laboratory signs because none of the available laboratory tests has sufficient specificity and sensitivity. A score that integrates clinical and laboratory findings has been developed, and has been shown to have good diagnostic accuracy. Serum ceruloplasmin is usually low, but may be normal in patients with active liver disease. The 24-h urinary Cu excretion is increased in 80% of patients, but may be normal, in particular in children without liver disease and in asymptomatic subjects. Non-ceruloplasmin-bound Cu is usually increased, but may be normal, in particular if ceruloplasmin is measured by immunoassay. Liver Cu is increased, but requires a liver biopsy and is not homogeneous across the hepatic tissue, in particular if patients have active disease and develop regenerative nodules. The Kayser-Fleischer ring is absent in most asymptomatic patients and in 50% of patients with hepatic WD. Genetic analysis of the *ATP7B* gene gives the diagnosis. Next-generation sequencing techniques have largely replaced biochemical tests. Molecular genetic screening should always be performed in asymptomatic siblings.

Treatment options include pharmacological therapy and liver transplantation. Medical treatment is lifelong and should not be discontinued, unless liver transplantation is performed.

Pharmacological therapy aims at achieving a negative Cu balance and preventing Cu re-accumulation [99]. Patients should be instructed to avoid Cu-rich foods including chocolate, nuts, shellfish, mushrooms, and liver, especially during the first year of treatment.

Chelating agents include D-penicillamine and trientine. D-penicillamine therapy has been the most commonly used chelating agent, and has been shown to reverse at least in part, most symptoms, including renal tubular dysfunction. Careful monitoring for side effects, including hypersensitivity reactions, proteinuria, Goodpasture's syndrome, polymyositis, systemic lupus erythematosus, skin changes, and bone marrow suppression, is essential. Trientine is another effective chelating agent and is often better tolerated than D-penicillamine. In addition to Cu, it also chelates iron, and should not be administered with iron supplements because it forms a toxic compound. Reversable sideroblastic anemia and lupus-like symptoms have been reported. Ammonium tetrathiomolybdate chelates Cu very efficiently, but at high doses can form an insoluble copper complex, which is deposited in the liver; it is not commercially available. Zinc salts interfere with the uptake of copper from the gastrointestinal tract and help reduce intestinal Cu absorption. They have few side effects. It may cause gastric irritation, mild immunosuppression, or pancreatic irritation. Successful therapy is assessed by monitoring serum non-ceruloplasmin-bound copper, and 24-h urinary Cu excretion. The 24-h urinary copper excretion on medication and after 2 days of cessation of therapy should be measured annually to assess the effectiveness of therapy and adherence to treatment. Treatment of presymptomatic patients and patients on maintenance therapy can be accomplished with a chelating agent or with zinc. During pregnancy, therapy should be decreased but not discontinued.

Patients with acute liver failure or decompensated cirrhosis, unresponsive to chelation treatment, should be offered liver transplantation; living-donor transplantation has been safely performed.

Lysinuric Protein Intolerance [100–102]

See ▶ Chap. 31, "Renal Manifestations of Metabolic Disorders in Children."

Microvillous Inclusion Disease

Microvillous inclusion disease (MVID) is a severe congenital intestinal malabsorption syndrome that presents with intractable secretory diarrhea within the first days or weeks of life. Patients are fully dependent on parenteral nutrition (TPN) for survival [103]. The disease is caused by biallelic mutations of the *MYO5B* gene (18q21.1) coding for myosin Vb, an actin-related motor protein that interact with endosomal Rab GTPases, allowing recycling to the plasma membrane [104]. Lack of expression of myosin Vb impairs apical brush border formation and cell polarity in enterocytes. FS has been reported in patients treated with TPN, but no clear ultrastructural defects of PT cells have been observed in kidney biopsies from these patients [105]. The diagnosis is made by intestinal biopsy and molecular genetic testing of *MYO5B*. Treatment is supportive and involves long-term maintenance of nutrition and hydration with TPN, and consideration of intestinal transplantation.

Maturity-Onset Diabetes of the Young (MODY)

Maturity-onset diabetes of the young (MODY) is characterized by autosomal dominant inheritance, onset before 25 years of age, absence of β-cell autoimmunity, and sustained pancreatic β-cell function. To date, pathogenic variants have been identified in at least 14 different genes [106]. MODY is a rare condition, accounting for 1–6% of pediatric cases of diabetes mellitus. Two subtypes (MODY1 and MODY5) show renal manifestations.

MODY1 is caused by variants in *HNF4A* (20q13.12), which encodes the transcription factor HNF4α. HNF4α is expressed in liver, pancreas, and kidney. Phenotypically, MODY1 manifests progressive insulin deficiency. Fetal *HNF4α* heterozygosity results in macrosomia due to hyperinsulinemia in utero and subsequent neonatal transient or persistent hypoglycemia, which is responsive to diazoxide. Hyperinsulinism remits during infancy, followed by a gradual decrease in endogenous insulin production and diabetes mellitus in adolescence [107]. Patients with the specific R76W variant manifest autosomal dominant FS in addition to neonatal hyperinsulinism, young onset diabetes mellitus, and macrosomia [108]. Nephrocalcinosis, renal impairment, hypercalciuria with relative hypocalcemia, and hypermagnesemia are also seen.

MODY5 is caused by variants in *HNF1B* (17q12) which encodes the transcription factor HNF1β [109]. HNF1β regulates organogenesis of the kidney, genitourinary tract, liver, lungs, gut, and pancreas. Renal malformations, including cysts, dysplasia, urinary tract malformation including hydronephrosis, hydroureter and vesicoureteral reflux, hypoplastic kidney disease, and rarely FS, are associated [110]. Carriers of *HNF1B* mutations can have significantly reduced birth weight. Patients manifest hypokalemia or hypomagnesemia in 60% of cases. They typically develop CKD in the fifth decade of life, and half of patients will progress to end-stage kidney disease without developing diabetic kidney disease. Genitourinary tract malformations (especially uterine abnormalities), liver dysfunction, and pancreatic hypoplasia have also been reported. Patients with MODY5 present with dyslipidemia, including a low high-density lipoprotein level and elevated triglyceride level.

Type IIa Sodium/Phosphate Cotransporter (NaPi-IIa) Deficiency

Mutations in the *SLC34A1* gene (5q35.3), which encodes type IIa sodium/phosphate cotransporter (NaPi-IIa), cause idiopathic infantile hypercalcemia with hypercalciuria and nephrocalcinosis, also termed infantile hypercalcemia type 2 [112] (see ▶ Chap. 40, "Renal Hypophosphatemia").

Two siblings with additional features of incomplete FS, including glucosuria, aminoaciduria, hyperuricosuria, and LMW proteinuria have been described. They carried a homozygous in-frame duplication of 21 bp in the *SLC34A1* gene. Unlike previously described *SLC34A1* mutations, both patients had normal serum calcium, no hypercalciuria and nephrocalcinosis, and moderate Vit D deficiency [111].

Arthrogryposis-Renal Dysfunction-Cholestasis (ARC) Syndrome

Arthrogryposis-renal dysfunction-cholestasis (ARC) syndrome is a fatal autosomal recessive multisystem disorder caused by variants in the *VPS33B* (15q26.1; homolog of the class C yeast vacuolar sorting protein) or *VIPAR* (14q24.3; VPS33B interacting protein, apical-basolateral polarity regulator, spe-39 homolog) genes. VPS33B and VIPAR are essential for lamellar body biogenesis and function [113]. The classical presentation of ARC syndrome includes congenital joint contractures, renal tubular dysfunction, and cholestasis. Additional features include ichthyosis, central nervous system malformation, platelet anomalies, and growth faltering. Diagnosis of ARC syndrome is based on clinical features with molecular genetic confirmation [113]. Patients manifests FS with glucosuria, aminoaciduria, phosphaturia, acidosis, and LMW proteinuria. In addition, they can have nephrogenic diabetes insipidus. Nephrocalcinosis, renal dysplasia, glomerular sclerosis, and tubular degeneration are reported [114]. There is no specific treatment and clinical management is supportive.

Idiopathic Fanconi Syndrome

Idiopathic FS is a diagnosis of exclusion, when no underlying cause can be identified. Whole exome sequencing of index cases and family members can help identifying a genetic cause.

Acquired Forms of Fanconi Syndrome

Endogenous Causes

Rarely, patients with nephrotic syndrome develop FS. Kidney histology usually shows focal segmental glomerulosclerosis, with or without tubulointerstitial changes [115, 119, 167]. Similarly, patients with autoimmune interstitial nephritis, including TINU syndrome (acute tubulointerstitial nephritis with uveitis), occasionally develop FS [119]. Corticosteroid therapy in these patients may improve tubular dysfunction.

Several other immunological or hematological disorders can be associated with FS, mostly in adults. These include Sjögren syndrome, multiple myeloma, monoclonal gammopathy, and lymphoma.

Sjögren syndrome is an autoimmune connective tissue disorder that affects exocrine glands [116]. Renal involvement of Sjögren syndrome is mainly manifests as tubular dysfunction. Seventy percentage patients manifest distal renal tubular acidosis [116]. Urinary concentration defects and LMW proteinuria are also often observed. Less than 5% of patients with Sjögren syndrome develop FS; they usually suffer osteomalacia, cortical bone thinning, and multiple fractures. Kidney histology shows chronic interstitial nephritis, with diffuse or focal lymphocytic infiltration. Treatment includes corticosteroid and immunosuppressant therapy.

FS is a typical finding in adults with myeloma, who have crystalline deposition of light chains in the cytoplasm of PT cells; the disease often progresses to severe tubulointerstitial nephritis and end-stage kidney disease.

Adult patients with paroxysmal nocturnal hemoglobinuria (PNH) can also manifest FS as a result of chronic hemoglobinuria and hemosiderin deposition in PT cells. By preventing intravascular hemolysis, anti-C5 therapy with eculizumab [117] significantly decreases the iron load to the kidney and the risk of developing FS.

Untreated children with distal renal tubular acidosis may present with features of FS, including LMW proteinuria, aminoaciduria and, less commonly, phosphaturia [122, 169]. Glycosuria is usually absent [169]. In one report, proximal tubular dysfunction was noted in 67% of patients with distal renal tubular acidosis at presentation [169]. The proximal tubulopathy is probably secondary to acidosis, as it resolves with treatment. A similar mechanism may explain cases of FS in association with anorexia nervosa, which improves with nutritional support [121].

Very rare cases of acquired FS have been reported after Legionella pneumonia infection [120].

Exogenous Causes

Drugs

A variety of drugs and herbs can cause FS (Table 2) [123]. The incidence of PT toxicity from these compounds is almost certainly underestimated. Most of these compounds are filtered by the glomeruli and reabsorbed in proximal tubular cells, where they accumulate at high concentrations, explaining the predominant toxicity of these drugs to this segment of the nephron. Various mechanisms are responsible for tubular epithelial cell toxicity, including direct damage of the brush border, inhibition of mRNA synthesis, mitochondrial toxicity, oxidative stress, abnormal lysosomal function, inhibition of endocytosis and intracellular trafficking, and altered phospholipid metabolism. The list of culprits is vast and includes anticancer agents, tetracyclines, aminoglycosides, rifampicin, salicylate [124], suramin, fumaric acid, valproic acid [125], and Chinese herbs [126]. These herbs contain aristolochic acids that cause PT injury, and the phenomenon is often referred to as “aristolochic acid-related nephropathy.”

A number of cancer chemotherapy agents cause FS. Their nephrotoxic effects are dose dependent and often irreversible. Ifosfamide (IFO) is an alkylating agent widely used in the treatment of solid tumors [127]. Patients treated with both IFO and cisplatin have a high risk of developing FS. Chloroacetaldehyde (CAA), one of the main metabolites of IFO, is probably responsible for its nephrotoxicity. CAA alters mitochondrial respiration, increases oxidative stress, decreases glutathione and ATP levels, inhibits intracellular trafficking, and alters expression of several genes [128, 129]. Electron microscopy performed on kidney biopsies of patients with IFO toxicity often shows irregular and enlarged mitochondria in PT cells. Ultrasound

Table 2 Causes of drug-induced renal FS. (Partly modified from Ref. [123]

Class	Drugs	Indications for use
Alkylating agents	Ifosfamide	Cancer
Aminoglycoside antibiotics	Gentamicin, amikacin	Gram-negative bacterial infection
Antiepileptics	Sodium valproate	Seizures, bipolar disorder
Anti-protozoals	Suramin	Trypanosomiasis
Chinese herbs	Aristolochic acid	Edema, health promotion
Dicarboxylic acids	Fumaric acid	Psoriasis
Iron chelators	Deferasirox	Iron overload
Nucleotide analogue reverse transcriptase inhibitors (NRTIs)	Didanosine, stavudine	HIV
Nucleotide reverse transcriptase inhibitors (NtRTIs)	Adefovir, cidofovir, tenofovir	HIV, hepatitis B, CMV
Platinum compounds	Cisplatin, carboplatin	Cancer
Salicylates	Aspirin	Analgesia, anti-inflammatory
Tetracycline antibiotics	Degraded tetracycline	Bacterial infection
Tyrosine kinase inhibitors	Imatinib mesylate	Chronic myeloid leukemia

usually shows hyperechogenicity, with preserved corticomedullary differentiation. A number of compounds, including L-carnitine, taurine, or N-acetyl cysteine, have been proposed to reduce IFO-induced nephrotoxicity [130], but to date, none have proved effective in the clinical practice.

Cisplatin enters PT cells through basolateral organic anion transporters and induces the formation of reactive thiols and monohydroxy complexes that are highly toxic to the PT cell [131]. In addition, it stimulates proapoptotic and inflammatory pathways, and inhibit several transporters [131].

Imatinib mesylate is a specific tyrosine kinase inhibitor that is used as first-line therapy for patients with chronic myeloid leukemia. This agent can induce partial FS including phosphaturia and uricosuria with AKI. Combined blockade of both platelet-derived growth factor receptor and c-Kit receptor tyrosine kinase in proximal tubules can also cause partial FS [132].

Nucleotide reverse transcriptase inhibitors that are used as anti-human immunodeficiency virus (HIV) agents including didanosine, stavudine, adefovir, cidofovir, and tenofovir can induce FS, nephrogenic diabetes insipidus, and acute renal failure [133–135]. Adefovir is also used for the treatment of chronic hepatitis B infection. Adefovir and cidofovir enter PT cells by basolateral organic anions transporters and efflux into the tubular lumen through the multidrug-resistance protein 2 (MRP2) located in the luminal membrane. If efflux is inhibited, these drugs accumulate in the proximal tubule cells, leading to mitochondrial damage and tubular toxicity. The cytotoxicity of adefovir and cidofovir is proportional to the expression of basolateral organic anions transporters (OAT). Histological and ultrastructural examination reveals degenerative changes of proximal tubules with swollen and dysmorphic mitochondria. Tenofovir is relatively less nephrotoxic, probably because it interacts less with OAT.

Nephrotoxicity can also result from crystallization of drugs within proximal tubules. Crystalline-induced tubular injury is exacerbated by low urinary flow rate and high concentration of the compound in the tubular lumen, when administered at high concentrations or with fast infusion rates. Examples include methotrexate, indinavir, acyclovir, atazanavir, sulfadiazine, ciprofloxacin, or triamterene.

Deferasirox, which prevents hemosiderin deposition in proximal tubules, rarely can cause reversible FS [136].

Other Chemical Compounds

A large number of chemical compounds exhibit PT toxicity. Paraquat, a nonselective herbicide, and colloidal bismuth subcitrate, both cause FS

[137, 138]. Large amounts of these compounds can be ingested in suicide attempts. Patients develop FS and AKI. Treatment with the chelating agent sodium-2,3-dimercapto-1-propanesulfonate in combination with hemodialysis is highly effective in reducing serum bismuth levels. Similarly, intoxication with other compounds, such as methyl-3-chromone (diachrome), 6-mercaptopurine, and toluene, can cause FS.

Heavy Metals

Heavy metals including lead, cadmium, mercury, chromium, and platinum are major environmental and occupational hazards. They are toxic at low doses, and induce mitochondrial toxicity and cell oxidative damage. The kidney is often the first organ affected. The extent of renal damage depends on the dose, route of intoxication, and duration of exposure. Both acute and chronic intoxications have been reported, with varying degrees of severity, ranging from subclinical tubular dysfunction to severe AKI [139]. Lead poisoning often leads to FS, in particular in children [140]. Since lead has a very long half-life, tubular dysfunction can persist for more than 10 years after severe poisoning [141].

Similarly, prolonged exposure to cadmium can cause FS [142]. Cadmium contained in the industrial waste in the Jinzu River basin in Toyama (Japan) was responsible for numerous cases of "*Itai-Itai*" (*ouch-ouch*) disease, which corresponds to FS associated with severe osteomalacia and frequent spontaneous fractures [143].

Therapy

Identification of the underlying cause of FS is the first step in establishing appropriate therapy. Avoidance of offending nutrients in galactosemia, HFI, and tyrosinemia, and avoidance of Cu-rich foods in Wilson disease are critical. Specific treatments with Cu-chelating agents detailed above can be effective for Wilson disease. Immunosuppressive drugs are used for immunological diseases, including Sjögren syndrome, TINU syndrome, or autoimmune interstitial nephritis. Exogenous substances should be stopped or reduced in dose if complete avoidance is not possible. Normalization of tubular function can occur after these treatments and withdrawal of toxic agents, but complete recovery of FS can take several months.

When a specific treatment is not available, therapy is aimed at ameliorating biochemical abnormalities secondary to renal solute and fluid losses and the metabolic bone disease. Proximal renal tubular acidosis usually requires large amount of alkali (2–15 mEq/kg of body weight per day) divided into four to six daily doses. Excessive alkali substitution may cause volume expansion, thereby exacerbating bicarbonate wasting. Potassium citrate, potassium bicarbonate, or potassium acetate treat both acidosis and hypokalemia simultaneously. Sodium wasting and dehydration are treated with combination of sodium bicarbonate, citrate, and chloride, depending on the degree of acidosis. Ensuring adequate fluid and electrolyte intake is essential, especially in the case of infants or gastrointestinal disease. Early intervention with intravenous replacement therapy may be required for patients with vomiting and diarrhea.

Hypophosphatemia and impaired renal vitamin D_3 metabolism can lead to rickets. This is treated with phosphate supplements and $1,25(OH)_2D_3$ or dihydrotachysterol, avoiding hypercalcemia and hypercalciuria, with may exacerbate nephrocalcinosis. Adequate physical activity, appropriate diet with calcium, phosphate, and vitamin D3 are recommended [144]. Growth faltering can be a major complication of FS. Despite treatment of electrolyte abnormalities, some patients manifest severe growth faltering, especially those with cystinosis and FBS. Growth hormone deficiency has also been reported in FS [145]. Treatment with growth hormone can improve growth in nephropathic cystinosis (see ▶ Chap. 37, "Cystinosis") and other selected cases.

Abstract

Cystinosis is an autosomal recessive disorder caused by mutations in the *CTNS* gene that encodes for cystinosin, a lysosomal cystine/H^+ symporter. The disease causes progressive accumulation of cystine in virtually all tissues. In the most frequent and severe form, termed nephropathic infantile cystinosis, kidney involvement is responsible for the initial symptoms, with patients presenting in the first year of life with symptoms related to renal Fanconi syndrome. Cystine corneal crystals are present in all patients by the age of 2 years. The diagnosis is based on the detection of increased leucocyte cystine levels and the demonstration of mutations in the *CTNS* gene. Cysteamine was introduced in the 1980s for the treatment of cystinosis. Cysteamine has considerably improved the prognosis of the disease and delays progression to end-stage kidney disease by approximately 10 years. If not appropriately treated, patients rapidly develop other symptoms, including retinal degeneration, hypothyroidism, diabetes mellitus, exocrine pancreatic insufficiency, pubertal retardation, gonadal dysfunction, restrictive pulmonary disease, myopathy, neurological deterioration, and liver involvement. Two milder forms of the disease, namely juvenile cystinosis and ocular cystinosis, have also been described. These patients present with milder symptoms later in childhood or with isolated corneal cystine depositions, respectively.

Introduction

Overview

Nephropathic cystinosis deserves a special place in the annals of clinical medicine as the first treatable lysosomal storage disease. The pathophysiology itself, based upon the formation of cystine crystals within the lysosomes of cells, is remarkable. The presence of cystine crystals provides a clue to the basic defect in cystinosis, i.e., failure to transport cystine out of lysosomes. This created a new area of biomedical investigation, explained the lysosome's function in salvaging small molecules for reutilization by the cell, and revealed a new category of lysosomal storage disorders due to transport defects rather than enzyme deficiencies. Even more striking, a rational therapy of cystine depletion (i.e., cysteamine) emerged, transforming nephropathic cystinosis from a universally fatal disease to a treatable chronic disorder with a decent quality of life and increased life span. Today, physicians can even observe the gradual dissolution of cystine crystals by cysteamine eyedrops bathing the corneas of patients' eyes.

History

Cystinosis was first described by Abderhalden in 1903, when understanding of its renal disease remained rudimentary. Fanconi, de Toni, and Debré recognized the renal tubular defect of cystinosis in the 1930s, and this complication retains the appellation renal Fanconi syndrome today. Generalized aminoaciduria was noted as a concomitant of nephropathic cystinosis in the late 1940s, and cystine storage within cellular lysosomes was proven in the late 1960s. By 1982, the basic defect of impaired lysosomal membrane transport of cystine was reported, and therapy with the cystine-depleting aminothiol cysteamine was shown to be safe and effective by 1987. Since then, numerous extrarenal complications of cystinosis have been described, and oral cysteamine therapy has been shown to delay or prevent virtually all of them.

The Basic Defect

Cystine has a molecular weight of 240 Daltons (Da) and consists of two molecules of cysteine joined by a disulfide bond. The equilibrium between cystine and cysteine depends upon their redox potentials and the pH of the milieu; if a high enough concentration of cystine is present (>2 mM), it may precipitate out of solution because of its poor solubility. Cysteine, which is very soluble, is produced by the hydrolysis of proteins; this occurs within lysosomes by the action of acidic hydrolases. Cysteine is then oxidized to cystine within lysosomes, where it accumulates if the cell has the genetic defect of cystinosis [1, 2]. Cysteine can also be transported from the cytosole to the lysosomal lumen by MFSD12 transporter on the lysosomal membrane [3]. After decades of study, scientists understood that cystine could not exit the lysosomes of cystinotic cells. Indeed, normal polymorphonuclear leukocytes were able to clear their lysosomes of cystine, but cystinotic cells could not [4]. Studies of isolated granular fractions, i.e., lysosomes, gave similar results [5]. In fact, normal, cystine-loaded lysosomes could transport cystine in either direction across their membranes, while cystinotic lysosomes couldn't release cystine [6, 7]. Cystine transport in neutrophil lysosomes was subsequently shown to be ligand specific, stereospecific, and ATP dependent [8, 9]. It displayed classical saturation kinetics (Fig. 1) and counter transport. Similar findings were observed in cultured lymphoblasts [7, 9]. In total, these discoveries proved that the process of lysosomal cystine transport is carrier mediated and deficient in cystinosis. Indeed, heterozygotes for cystinosis displayed half the maximum velocity of cystine transport [10], consistent with having half the normal number of cystine carriers (Fig. 1). The later discovery of the cystinosis gene, *CTNS*, and studies of its gene product, cystinosin, demonstrated that this protein does indeed transport cystine, in a process driven by the hydrogen ion gradient across the lysosomal membrane [11, 12].

Cell damage in cystinosis is probably not related solely to lysosomal cystine accumulation. Recent studies have revealed cell abnormalities that are directly caused by defects in the cystinosin protein, independent of its transport activity [13, 14]. Supporting this view, not all aspects of the cell's cystinotic phenotype are corrected after lysosomal cystine depletion by cysteamine, which possibly explains why this drug, which has dramatically changed the outcome of cystinosis, cannot treat all symptoms completely. In particular, the Fanconi syndrome of cystinosis occurs in infancy, about the same time that renal tubules appear damaged early in

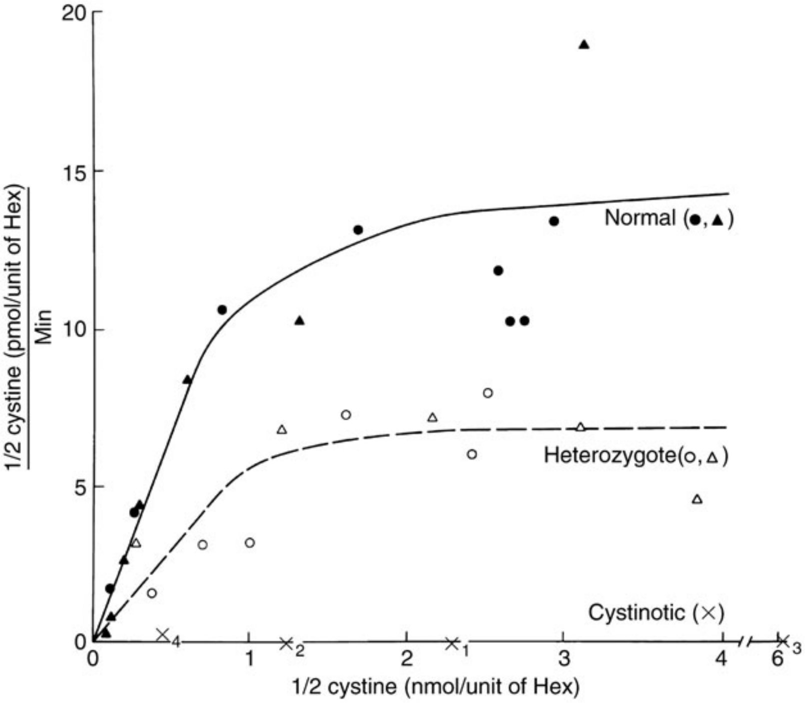

Fig. 1 *Lysosomal cystine transport in leukocyte granular fractions*. Normal lysosomes were loaded with cystine by exposure of whole leukocytes to cystine dimethylester, which is hydrolyzed to cystine within the acidic lysosome. Cystinotic lysosomes contain endogenously produced cystine. The abscissa gives the level of cystine loading per unit of hexosaminidase, i.e., per lysosome. The ordinate gives the rate of cystine egress in picomoles per minute per unit of hexosaminidase. Normal lysosomal cystine egress exhibits saturation kinetics, while cystinotic lysosomes show virtually no cystine egress. Heterozygotes for cystinosis, with half the number of lysosomal cystine transporters, display half the normal maximal velocity of cystine egress. (Reprinted from SCIENCE [5])

renal development [15]. Cells obtained from cystinotic patients or that have been generated in knockout experimental models are characterized by impaired endolysosomal dynamics and abnormal autophagy resulting in the accumulation of autophagosomes, mitophagosomes, and enlarged lysosomes around the perinuclear region. Studies have documented altered mTORC1 activity that is probably linked to altered interactions between cystinosin and proteins of the vacuolar ATPase, resulting in the activation of the transcription factor EB (TFEB). In proximal tubular cells, impaired endolysosomal trafficking compromises the recycling to the plasma membrane of the endocytic receptors megalin and cubilin, causing low-molecular weight proteinuria, as seen in Fanconi syndrome. Cell death may result from oxidative stress, mitochondrial damage, or direct stimulation of apoptosis. Impaired efflux of cystine from lysosomes has also been proposed to alter glutathione metabolism, exposing cells to oxidation. In proximal tubular cells, accumulation of large cystine crystals may rupture cell membranes directly, causing cell death. In addition, cystine crystals activate inflammatory pathways through NOD-like receptors. Despite these remarkable advances in the understanding of the physiopathology of the disease, it remains unclear which events are key elements causing cell dysfunction versus which represent downstream events.

Pathology

Patients who have not received long-term cystine-depleting therapy exhibit specific pathological features. As a consequence of excessive cellular cystine storage (to 10–1000 times normal levels), patients with cystinosis develop microscopic crystals of cystine, apparent within lysosomes on electron microscopy [2]. Tissues containing cystine crystals include the cornea, conjunctiva, iris, retina, liver, spleen, kidneys, intestines, rectal mucosa, pancreas, testes, lymph nodes, bone marrow, macrophages, thyroid, muscle, and choroid plexus [6, 16]. The crystals are generally hexagonal or rectangular and appear birefringent under polarizing light (Fig. 2). Tissue damage accompanies the intracellular cystine accumulation of cystinosis, with the greatest effects in the kidney. Renal tubules show a characteristic narrowing called a swan-neck deformity [15, 17], followed by interstitial nephritis and endothelial glomerular proliferation, necrosis, and hyalinization. Formation of atubular glomeruli and a glomerulo-tubular disconnect appears to represent a maladaptation to renal injury, contributing to the progression of renal insufficiency [17, 18]. Crystals are occasionally seen within glomeruli, which often contain large multinucleated podocytes [19]. Focal and segmental glomerulosclerosis (FSGS) lesions in cystinotic glomeruli can be undistinguishable from idiopathic FSGS. In the eye, the retina exhibits patchy hypopigmentation [20] and crystals appear occasionally in the iris and rarely in the retina [21] [22]. In older patients, the thyroid and testes appear fibrotic. Muscle histopathology involves a late vacuolar myopathy with variation in fiber size, atrophy of type I fibers, and ring fibers [23, 24]. In the liver of untreated adults, nodular regenerative hyperplasia can occur [25].

Genetics

Cystinosis is an autosomal recessive disorder, and heterozygotes never present clinical symptoms. The disease occurs with an incidence of approximately one in 100,000–200,000 live births, although there are genetic isolates of cystinosis, including one with a frequency of 1 in 26,000 in Brittany [26] and another among French Canadians. Within the US population, it is estimated that approximately one in 200 individuals carries a cystinosis (i.e., *CTNS*) mutation. A recent newborn screening program in Germany has identified 696 heterozygous carriers among 257,734 newborns, corresponding to a carrier frequency of one in 370 [27]. These numbers allow counseling of persons, known to be heterozygotes because a family member was diagnosed, with respect to their risk of having a child with cystinosis by an unrelated mate.

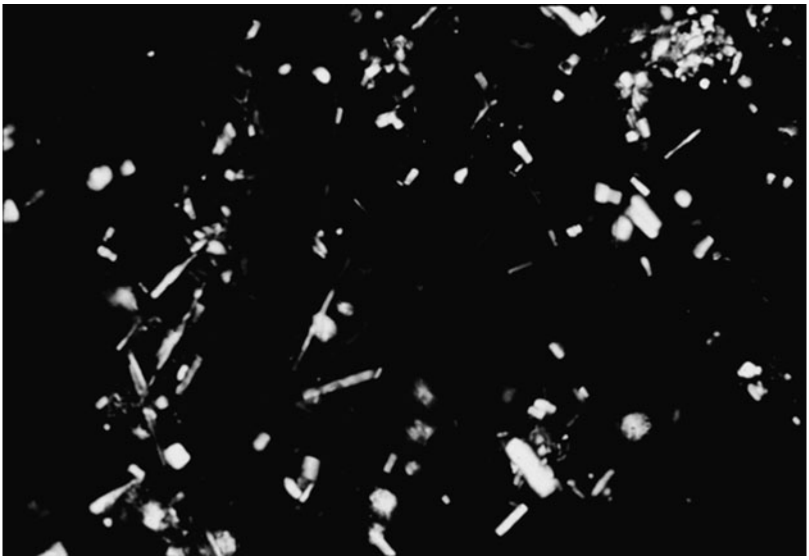

Fig. 2 *Birefringent cystine crystals in cystinosis tissue under light microscopy.* Note rectangular and needlelike shapes. Some crystals are undergoing dissolution due to the aqueous fixative

The *CTNS* Gene

The cystinosis gene was mapped to chromosome 17p13 in 1995 [28] and identified in 1998 [11]. It contains 12 exons within 23 kb of genomic DNA and codes for a 367-amino-acid protein, cystinosin, with seven transmembrane domains. The function of cystinosin as a cystine transporter has been demonstrated [12]. Over 160 different *CTNS* mutations, including deletions, insertions, nonsense, missense, and splice site mutations, have been reported in the Human Gene Mutation Database; they are found in different combinations in individuals with cystinosis [29–31]. The promoter [32], leader sequence, transmembrane regions, and non-transmembrane regions are affected by different mutations. The most common mutation is a 57,257-bp deletion removing the first 9 exons and part of exon 10 of *CTNS* [32, 33]. This deletion arose in Germany ~500 AD and is present in the homozygous or heterozygous state in more than half of cystinosis patients of European descent [33]. Homozygosity for this deletion might be associated with a slightly greater frequency of non-renal complications of cystinosis in adulthood and of enhanced intrinsic skin aging [31, 34]. Hotspot mutations other than 57-kb deletion are reported in different populations [31].

Clinical Aspects

Cystinosis Variants

Traditionally, cystinosis has been divided into three subtypes [6]. Infantile nephropathic cystinosis (OMIM 219800) is the classic disease, described below and comprising 95% of cases. Affected individuals have two severe *CTNS* mutations. Patients with intermediate (formerly termed “juvenile” or “adolescent” cystinosis; OMIM 219900) cystinosis have milder disease, with diagnosis in childhood, adolescence, or early adulthood; they eventually develop renal failure. Intermediate patients account for less than 5% of cases and generally carry one severe and one mild *CTNS* mutation [31, 35]. These patients usually present with asymptomatic proteinuria and mild or absent tubulopathy. Over time, they develop lesions that may be misdiagnosed as primary focal segmental glomerulosclerosis [35].

Patients with ocular cystinosis (formerly termed “adult” or “benign” cystinosis; OMIM 219750) never exhibit renal failure or retinal hypopigmentation, but have cystine crystals in their bone marrow and corneas [6]. They do have measurable residual cystine-transporting capacity in their polymorphonuclear leukocytes’ lysosomes [36]. The only clinical manifestation of ocular cystinosis is photophobia, and patients are generally diagnosed incidentally on eye examination that includes the use of a slit lamp. There exist approximately 20 ocular cystinosis patients, who have either one mild and one severe or two mild *CTNS* mutations [37]. The distinction among the three types of cystinosis is in part artificial, since there exists a continuum of disease severity rather than discrete categories.

Early Clinical Manifestations

As for patients with several other lysosomal storage disorders, individuals with cystinosis appear entirely normal at birth. Nevertheless, the disease eventually affects nearly every tissue of the body, with variable times of onset. The signs and symptoms can be described as early and late findings, demarcated roughly by adolescence. The earliest manifestations of cystinosis involve complications of renal Fanconi syndrome and growth retardation [16].

Renal Tubular Fanconi Syndrome with Rickets

Cystinosis is the most common identifiable cause of renal Fanconi syndrome in early childhood (see ▶ Chap. 36, “Pediatric Fanconi Syndrome”). Although the proximal tubulopathy does not respond well to cysteamine, cystinosis is a treatable disease and, therefore, should be considered first when renal tubular solute wasting is recognized. In cystinosis, Fanconi syndrome is not evident at birth but generally appears at 6–12 months of age, with variable severity. In the past, and even now, in low-resource countries, infants have died of the dehydration and electrolyte imbalance associated with the Fanconi syndrome, without the benefit of a diagnosis. The Fanconi syndrome of cystinosis is nearly always complete and includes failure to reabsorb water, metabolic acidosis, electrolytes disturbances (hypokalemia and occasional hyponatremia), urinary losses of minerals (phosphaturia, hypocalcemia, and hypomagnesemia), amino acids, carnitine, glucose, and small-molecular-weight proteins (see chapter Fanconi syndrome). The clinical presentation of the Fanconi syndrome includes polyuria (often 2–3 L per day in small children and sometimes up to 5–6 L per day), dehydration (sometimes with consequent fevers), and polydipsia. Large volumes of fluid intake fill the stomach and reduce appetite. Phosphate and calcium wasting cause rickets, with low serum phosphate and calcium, and elevated alkaline phosphatase levels. In some cases, significant hypocalcemia triggers secondary hyperparathyroidism, exacerbating bone reabsorption. Children may fail to walk because of the bone pain of rickets, and they exhibit tender, swollen wrists and ankles due to metaphyseal widening. In severe cases, frontal bossing, a rachitic rosary, and genu valgum/varum develop. Osteoporosis and epiphyseal fraying are visible on radiographs. The combination of hyperphosphaturia and hypercalciuria may result in medullary nephrocalcinosis. Hypocalcemia can cause painful episodes of tetany or even seizures, especially 20–30 min after a dose of an alkalinizing medication that lowers circulating concentrations of ionized calcium.

Glomerular Damage

Cystinosis accounts for 1–5% of chronic renal failure in children [38, 39]. By the time a typical infant with cystinosis is diagnosed at approximately 1 year of age, significant renal damage has already occurred. It has been postulated that rapid progress to renal damage could be explained by inflammation caused by cystine crystals [40]. Early podocyte injury is likely to coexist along with proximal tubular dysfunction contributing to renal disease progression [41]. A reasonable estimate would place the creatinine clearance at the time of diagnosis at approximately 70% of normal, and this level of function slowly but inexorably decreases. Without treatment, most children with cystinosis have reached end-stage kidney disease (ESKD) by age 10 and require transplantation or dialysis. In a European study of 205 children with cystinosis, the mean age for ESKD was 9.2 years. Chronic kidney disease in cystinosis resembles that of other renal disorders, but growth retardation, osteodystrophy, and anemia are often more severe. Blood pressure may increase as kidney function declines, but cystinosis per se is not a risk factor for developing hypertension.

Growth Impairment

Newborns with cystinosis exhibit normal height, weight, and head circumference. While head circumference is maintained, height and weight percentiles generally fall by 6–12 months of age; failure to thrive is often the first indication of the diagnosis. By 1 year of age, the average infant with cystinosis has a height at the third percentile [42]. Without treatment, growth continues at 50–60% of the normal rate (Fig. 3). Weight usually follows height, but with greater variability. In patients not receiving growth hormone therapy, bone age usually lags behind chronological age by 1–3 years. Children with retarded bone age retain growth potential past the usual age of epiphyseal closure, but height is never gained past age 20, regardless of the bone age. The cause of impaired growth has not been definitively determined. Growth hormone levels are usually normal [43], but patients may have abnormal kinetics of growth hormone secretion after glucagon stimulation [44] and respond to supraphysiologic doses of recombinant growth hormone [45]. Hypophosphatemic rickets, acidosis, poor nutrition, and renal insufficiency probably all contribute to the poor growth of cystinosis. In addition, cystinosis patients develop a distinct form of chronic kidney disease–mineral and bone disorder (CKD-MBD), characterized by lower levels of fibroblast growth factor-23 (FGF-23) and

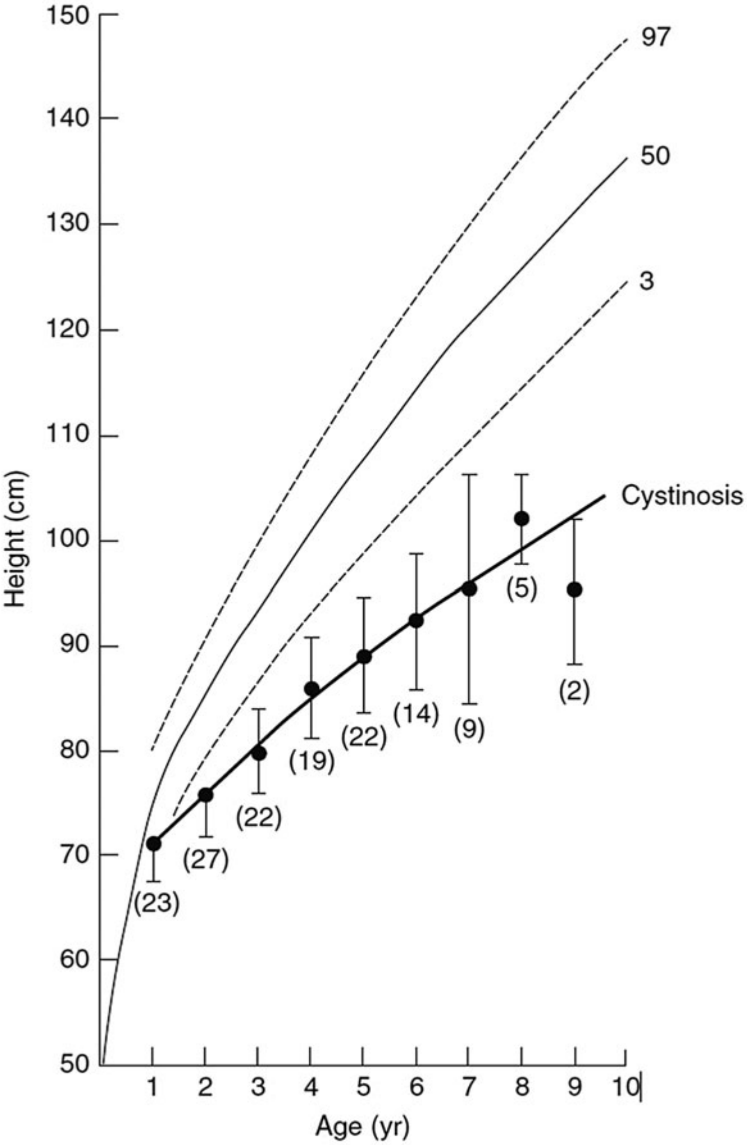

Fig. 3 *Natural history of growth in children with cystinosis*. Mean values for cystinosis children are superimposed upon a normal growth chart. On average, a child with cystinosis falls from normal height to the third percentile at 1 year of age and continues to grow slowly so that the height age is 4 years when the chronological age is 8 years. (Reprinted from the New England Journal of Medicine [42])

parathyroid hormone (PTH), even in advanced stages, that are related to persistently decreased renal phosphate reabsorption [46, 47, 48]. Patients with nephropathic cystinosis are, on average, shorter than children with similar degrees of kidney failure due to other causes.

Ocular Involvement

The primary ophthalmic manifestation of cystinosis is photophobia. This occurs due to corneal crystals that first appear in the anterior third of the cornea [49]. Corneal crystals are always present by 16 months of age on slit lamp examination and are diagnostic for cystinosis [50]. The number of crystals increase with age, reaching a maximum density by 8 years of age. An atlas of corneal crystal density at different ages has been published [50]. In vivo confocal microscopy (IVCM) and anterior-segment optical coherence tomography (AS-OCT) allow for more accurate quantification of corneal crystal deposition [49, 51]. Crystal density among patients with ocular cystinosis appears less than that in patients with classical disease. Children with cystinosis complain of sensitivity to light at variable ages, but usually not until 5–10 years of age. They squint to the point that, without treatment, they can eventually develop blepharospasm refractory to all modes of therapy. Often, patients wear dark glasses outside and turn down the lights inside. Occasionally, a child with cystinosis may experience a corneal ulceration as a crystal breaks through the corneal epithelium. This complication, which resolves spontaneously, occurs much more frequently in adolescence and adulthood, when haziness of the cornea often appears, but has become very rare in patients who have been treated with topical and systemic therapy since early in life.

Hypothyroidism

In the natural history of cystinosis, approximately half of patients exhibit hypothyroidism by age 10 [52] and 90% by age 30 [53], with low thyroxine and free T4 levels and elevated TSH levels. In cystinosis, the thyroid tissue appears fibrotic with occasional crystals present. In mice with cystinosis, hyperplasia and hypertrophy of thyroid follicles precede colloid exhaustion [54]. Treatment with cysteamine remarkably delays and possibly prevents the development of hypothyroidism.

Cognition and Psychological Aspects

Children with cystinosis learn normally and have low normal full-scale IQs [55–57]. However, isolated deficits in visual processing [58], tactile recognition [59], and short-term visual memory have been reported [59]. The neurocognitive profile is further characterized by significant discrepancies between perceptual reasoning and verbal comprehension, and impairment of working or auditory sensory memory [57]. Brain MRI shows cortical and subcortical brain atrophy, especially in parieto-occipital regions, resulting in lower total IQ scores observed in patients with atrophic brains [57, 60]. Patients with cystinosis may exhibit behavioral and social problems, which are related in part to their chronic disease, burden of therapy, and uncertainty of prognosis [60, 61].

Other Clinical Findings

Children with cystinosis are notoriously poor eaters, with craving for salty foods such as pickles, ketchup, and potato chips. In addition, many children exhibit a pica for hot foods such as jalapeno peppers, and tabasco sauce, possibly related to the functional loss of the capsaicin- and heat-sensitive ion channel TRPV1 in patients harboring the 57-kb deletion [62]. Young children and infants have an increased tendency toward vomiting, which is more severe in the morning prior to eating. Some of this may be related to medications. Excessive water intake with increased thirst causes abdominal distention and a sense of fullness, which further contributes to nausea, vomiting, and poor appetite. The nausea and vomiting often decrease with age and generally cease by 7–8 years of age. Rarely, a patient may suffer from decreased gastrointestinal motility and have projectile vomiting upon eating or drinking. One-third to one-half of children 10–18 years of age have mild hepatomegaly on physical examination [52], with no identifiable cause. Patients from lightly pigmented backgrounds appear less pigmented than other family members. This probably reflects dysfunction of melanosomes, which are lysosome-related organelles [63]. Patients of African or Asian descent have pigmentation, but often slightly less compared to their siblings. Most patients manifest decreased sweat production, causing flushing, heat avoidance, and occasional hyperthermia [64]. In addition, tear and saliva production is often reduced in cystinosis. Enuresis in children with cystinosis may reflect the large volume of urine produced daily. Idiopathic intracranial hypertension, or pseudotumor cerebri due to non-absorptive hydrocephalus, has been reported in several patients and has been attributed, in part, to cystinosis itself [65, 66]. Rarely, optic nerve compression due to idiopathic intracranial hypertension has caused blindness in cystinosis.

Diagnosis

Because a safe and efficacious treatment exists for cystinosis, physicians should maintain a high index of suspicion in patients demonstrating any characteristic findings. Unfortunately, the average

age of diagnosis for cystinosis remains just over 1 year, and even today several patients escape detection for years despite manifesting typical signs and symptoms.

Postnatal Diagnosis

A family history of cystinosis will naturally point to this disease in a child with suggestive findings. However, even without a previously affected sibling, evidence of renal tubular Fanconi syndrome should prompt investigation for cystinosis. Other signs include poor growth, failure to walk at an appropriate age, or evidence of rickets. The presence of typical corneal crystals on slit lamp examination by an experienced ophthalmologist will establish the diagnosis. Such crystals are usually not apparent within the first several months of life, but crystals are always present by 16 months of age [50]. Elevated intracellular-free cystine concentrations also are diagnostic. Patients have high concentrations of cystine in a variety of cell types, but polymorphonuclear leukocytes are the preferred cells in which to perform measurements [6, 13, 16, 67, 68]. While affected lymphocytes have three- to fivefold elevations above normal cystine concentrations, neutrophils have 30–100 times the normal levels, i.e., 3–23 nmol half-cystine/mg protein (normal, <0.2) [69]. Units of half-cystine are employed by convention, because early assays did not distinguish cystine from cysteine. Patients with intermediate cystinosis generally have values at the lower end of the nephropathic range, and patients with ocular cystinosis have values of 1–5 nmol half-cystine/mg protein [70]. White blood cell heterozygous values are less than 1 nmol half-cystine/mg protein. Several methods for intracellular cystine analysis have been used in the past, but these has been progressively replaced by liquid chromatography–tandem mass spectrometry [71, 72]. Approximately 3–10 mL of acid-citrate blood is required to isolate polymorphonuclear leukocyte-rich fractions. Red blood cell and lymphocyte contamination increase the protein in the denominator, causing underestimation of the cystine concentration. Sample storage at room temperature for >12–24 h may also cause spuriously low values. Immuno-magnetic beads allow isolation of granulocytes up to 30 h after blood sampling [73]. Limited sensitivity of the assay is required for diagnosis, but higher sensitivity is necessary for monitoring treatment efficacy. In the past, tissue biopsies (kidney, bone marrow, rectal mucosa, or conjunctiva) were used for diagnosis, but are no longer indicated. *CTNS* gene mutation analysis confirms the diagnosis; multiplex PCR allows rapid identification of the common 57,257-bp deletion. Cystinosis is a monogenic disease. The mutation detection is very high. Very few intronic mutations requiring sequencing of mRNA products for diagnosis have been reported [74]. Newborn screening allows for early diagnosis and treatment, which should result in improved long-term prognosis [75]. Two methods have been proposed: (a) tandem mass spectrometry for the determination of derivative seven-carbon (C7) sugars in dried blood spots (DBS) that can only detect homozygous 57-kb deletions of the *CTNS* gene and (b) molecular testing using next-generation sequencing techniques that allow detection of the most common *CTNS* mutations [76, 77].

Prenatal Diagnosis

Cystinosis can be diagnosed prenatally. When the mutation is known, molecular diagnosis can be performed on chorionic villus samples or on circulating fetal nucleated cells. Chorionic villus cells can also be assayed directly for cystine content, if enough material is available [78, 79].

Heterozygote Detection

Carrier (heterozygote) detection by leukocyte cystine measurement may be problematic. While carrier levels can be as high as 1 nmol half-cystine/mg protein, they can also be within the normal range, especially when cystine is measured on mixed white blood cells and not on purified granulocytes [67]. Molecular diagnosis is the preferred method to diagnose carriers.

Differential Diagnosis

Polyuria, hypokalemia, and glucosuria associated with renal Fanconi syndrome can sometimes lead to the mistaken diagnosis of nephrogenic diabetes insipidus, Bartter syndrome, or diabetes mellitus. Once true Fanconi syndrome is diagnosed, cystinosis should be considered first, before considering other causes of proximal tubular dysfunction (see ▶ Chap. 36, "Pediatric Fanconi Syndrome"). The vitamin D–resistant hypophosphatemic rickets of cystinosis has been mistaken for vitamin D deficiency or for other genetic forms of rickets (see ▶ Chap. 40, "Renal Hypophosphatemia"). Rarely, patients have carried the diagnosis of FSGS or simply kidney insufficiency until crystals were discovered upon removal of the native kidneys at transplant. Conversely, cystinosis was mistakenly diagnosed in a patient with idiopathic nephrocalcinosis but without intracellular cystine storage. Cystinosis should not be confused with cystinuria, in which cystine, arginine, ornithine, and lysine fail to be properly reabsorbed by renal tubular cells (see ▶ Chap. 54, "Urinary Stone Disease and Nephrocalcinosis"). In cystinosis, generalized aminoaciduria occurs because of the Fanconi syndrome, but there is no particular elevation in urinary cystine, and no diathesis toward renal stone formation, except in rare cases with severe hypercalciuria and nephrocalcinosis.

Therapy

Treatment of nephropathic cystinosis can be divided into symptomatic modalities for particular organ complications and cystine-depleting therapy directed specifically at reducing the cystine content of all cells of the body.

Replacement of Renal Losses

Renal tubular Fanconi syndrome results in wasting of small molecules, which need to be replaced (also see ▶ Chap. 36, "Pediatric Fanconi Syndrome"). First, there must be free access to water and bathroom privileges. Dehydration can accelerate the progression of renal failure. At the same time, electrolytes must be supplied. Sodium should not be restricted, and affected children should be permitted to indulge their natural cravings for salty foods. Potassium generally needs to be supplemented as either chloride, gluconate, or citrate salts. For alkalinization, citrate or bicarbonate salts of potassium or sodium can be used [80]. Phosphate is provided as potassium or sodium salts. Electrolytes, alkali, and phosphate salts should be administered every 6 h to ensure stable plasma levels. Vitamin D, as calcitriol or alfacalcidol in therapeutic doses, fosters gastrointestinal absorption of phosphate and calcium, although patients are not naturally deficient in vitamin D. With adequate phosphate and calcium replacement, monitored by serum alkaline phosphatase levels, rickets generally resolves in 3–6 months, although osteoporosis may persist on radiography. Children with hypocalcemia require calcium to treat their rickets and to prevent tetany. If calcium supplementation is required, care must be taken to separate the administration of calcium and phosphate by at least 60 min to prevent precipitation of calcium phosphate in the gut [81]. Rarely, patients require magnesium and oral carnitine supplementation. Doses of replacement medications should be monitored regularly in growing children. After the adolescent growth spurt, decreased amounts of supplemental phosphate are generally required to minimize the development or progression of nephrocalcinosis [82]. Dehydrated children with cystinosis require large amounts of fluid and electrolytes for effective rehydration. As chronic kidney failure progresses, cystinosis patients usually do not become oliguric, hyperkalemic, or hyperphosphatemic, until reaching advanced disease or end-stage kidney failure.

Other Symptomatic Treatments

The poor eating habits, nausea, vomiting, and early satiety due to excessive fluid ingestion all contribute to poor nutrition, especially around the time of diagnosis. Nutritional consultations can prove critically important to ensure, for example, that ingested fluids contain calories whenever possible. Many (but not all) infants and toddlers require feeding tubes to achieve adequate nutrition and sufficient hydration, and there should be a very low threshold to inserting feeding tubes. Once mineral, electrolyte, and acid–base balance are established, children can begin to eat normally. Most children eat well by 6–10 years of age and do not require feeding tubes. An occasional child requires gastric tube access for medications, hydration, or calories, but maintenance of the masticatory process is very important. Some nephrologists prescribe angiotensin-converting enzyme inhibitors to reduce proteinuria, based upon the potential benefit of this therapy in maintaining renal function in many chronic kidney diseases. The efficacy of this practice with respect to glomerular function has not been proven in cystinosis. If prescribed, angiotensin-converting enzyme inhibitors should always be used prudently, especially in patients with severe polyuria, and not in association with indomethacin to avoid compromising renal perfusion. Some patients, especially those in Europe, receive indomethacin to reduce urine volume [80, 83]. Indomethacin administration is generally reserved for young patients, particularly if they have huge urine volumes and severe growth retardation. In the past, most patients with cystinosis required thyroid hormone replacement, but treatment with cystine-depleting therapy has reduced the number of patients who require L-thyroxine supplementation [53, 84]. Some children benefit from judicious use of anti-emetics, which are most often taken just before the breakfast meal. The impairment of sweating predisposes to heat prostration, so children should avoid prolonged periods in the sun. Exercise helps to maintain muscle strength in the face of nutritional challenges. Skeletal deformities should be addressed in a timely fashion, and patients with severe rickets or renal osteodystrophy may require corrective orthopedic surgery such as an osteotomy [81]. Physical therapy is critical for such patients to correct abnormal body alignment, maintain muscle tone, and prevent further skeletal abnormalities such as scoliosis later in life. Although patients possess normal amounts of growth hormone, they may still benefit from growth hormone supplementation if GFR is above 50 ml/min/1.73 m [45]. Caution should be used however, in prescribing growth hormone in children with hyperparathyroidism. Supplementation of renal losses, appropriate caloric intake, and cysteamine therapy (see below) can achieve normal growth rate within 6–12 months, although it will not usually allow for catch-up growth. Hence, if children remain below the third percentile for height a year after their medications have been adequately received, growth hormone should be considered [81].

Renal Replacement Therapy and Kidney Transplantation

No particular findings distinguish patients with cystinosis from other children and young adults requiring renal replacement therapy. Once a person with cystinosis reaches ESKD, renal replacement therapy with hemodialysis, peritoneal dialysis, or renal transplantation is required. Cysteamine clearance during dialysis does not require dose adaptation [85]. With specific regard to renal transplantation, carriers of *CTNS* mutations are suitable candidates as kidney donors. Cystinosis does not recur in the transplanted kidney, because the lysosomal cystine transport defect is intrinsic to the host cells. Nevertheless, a graft biopsy can sometimes contain cystine crystals due to infiltration of the donor kidney by host macrophages. Overall kidney graft survival is excellent and is, on average, superior to that for other conditions [86, 87]. Nonetheless, patients with cystinosis should receive standard antirejection therapy. Steroid-free immunosuppression is recommended in patients without additional risks of rejection. While current practice recommends retention of host kidneys, if some native kidney function remains, blood flow to the host kidneys may result in persistence of the Fanconi syndrome post-transplant. Polyuria may occasionally be problematic, and potassium supplementation may be needed after renal transplantation. Most of the renal osmotic load, however, is handled by the transplanted kidney and losses from native kidneys usually resolve in the first months following transplantation. After a renal allograft, patients virtually always improve in activity, appetite, and feeling of well-being. Patients grow significantly after transplantation, at rates that depend upon chronological age and bone age.

Oral Cysteamine Therapy

Many putative cystine-depleting regimens have proven unsuccessful in cystinosis patients, including restriction of sulfur-containing amino acids and the administration of ascorbic acid, dithiothreitol, and penicillamine [88]. One specific radioprotective agent, however, has proven efficacious. In 1976, the aminothiol cysteamine, or beta-mercaptoethylamine [89], was shown to deplete affected fibroblasts in vitro, and polymorphonuclear leukocytes in vivo, of cystine. Cysteamine passes through the plasma and lysosomal membranes into the lysosome, where the acidic environment puts a charge on the amine group and traps the molecule. Within the lysosome, cysteamine interacts with cystine in a disulfide interchange reaction to produce cysteine and cysteine–cysteamine mixed disulfide, both of which readily exit the lysosome without requiring a functional cystine transporter (Fig. 4). Cysteine can exit lysosomes through its own carrier, while the mixed disulfide exits through the cationic amino acid transporter PQLC2 [90]. In the cytosol, cysteine participates in normal cytoplasmic reactions and can be eliminated from cells.

When taken orally, cysteamine removes up to 95% of leukocyte cystine within 1 h of ingestion. Parenchymal cells are thought to respond in a similar fashion, although the extent and time course of depletion remains unknown for other tissues. A clinical trial of oral cysteamine therapy was initiated in 1978 [42]. By the end of the study in 1985, the cysteamine-treated group had significantly better kidney function than the untreated group (39 vs. 30 mL/min/ 1.73 m^2), despite being

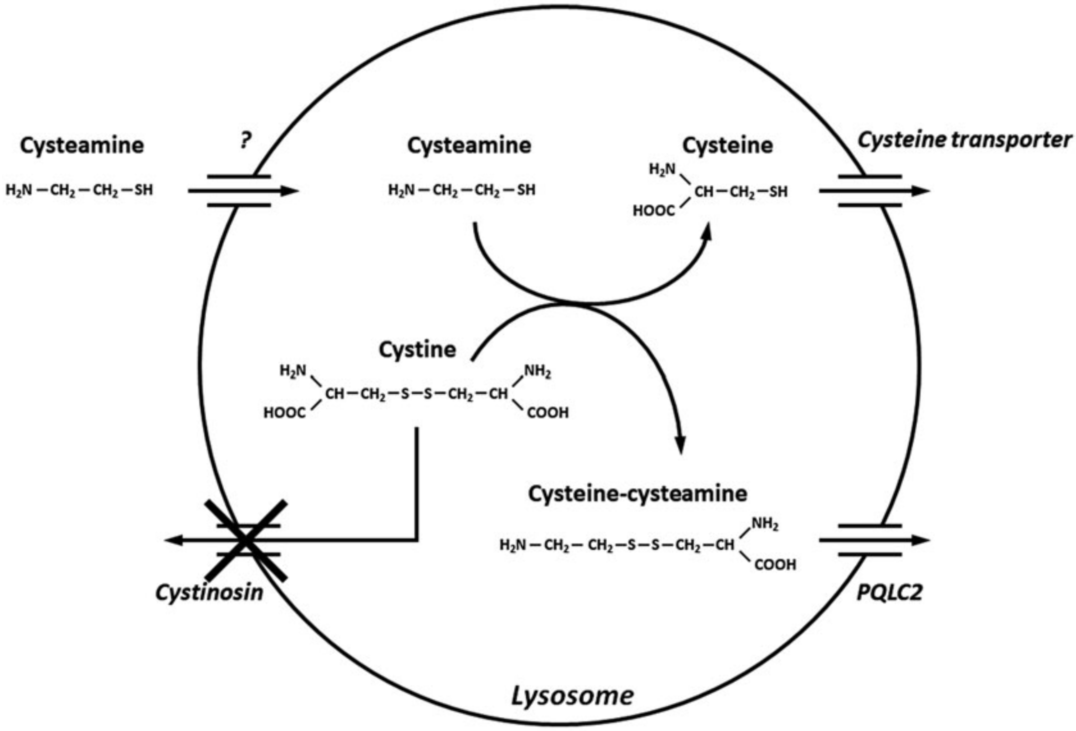

Fig. 4 *Mechanism of action of cysteamine*. The free thiol enters the lysosome and reacts with cystine (Cys-Cys), which cannot exit the cystinotic lysosome. The two products, cysteine and cysteine–cysteamine mixed disulfide, can readily leave the cystinotic lysosome; the mixed disulfide leaves through the PQLC2 transporter. This process lowers lysosomal cystine levels by over 90%

1.4 years older. Growth velocity was also better in the cysteamine-treated group. Based on this report, oral cysteamine became the treatment of choice for patients with nephropathic cystinosis prior to transplantation. Subsequent studies, including a seminal intent-to-treat analysis in 1993 [91], verified the safety and efficacy of chronic oral cysteamine therapy and demonstrated that patients treated early and effectively had a mean creatinine clearance of 57 mL/min/1.73 m^2 at a mean age of 8.3 years. At the same age, 60% of children without cysteamine treatment had progressed to ESKD and children with suboptimal treatment had outcomes between these extremes (Fig. 5). Cysteamine not only slowed the deterioration of glomerular function, but also allowed for normal increase of kidney function in the first 3 years of life [91]. Consequently, early initiation of cysteamine was deemed critical; every month of treatment in the first 2 years of life translates into 14 months of preservation of kidney function later in life. The optimally treated patients also grew at a normal rate, parallel to normal height curves, while remaining below the third percentile on average [6].

Cysteamine bitartrate was approved for treatment of cystinosis as Cystagon® in 1994 and 1997 in the USA and Europe, respectively. Cystagon® is given at a dose of 60–90 mg/kg/day or 1.3–1.95 g/m^2/day, in divided doses every 6 h

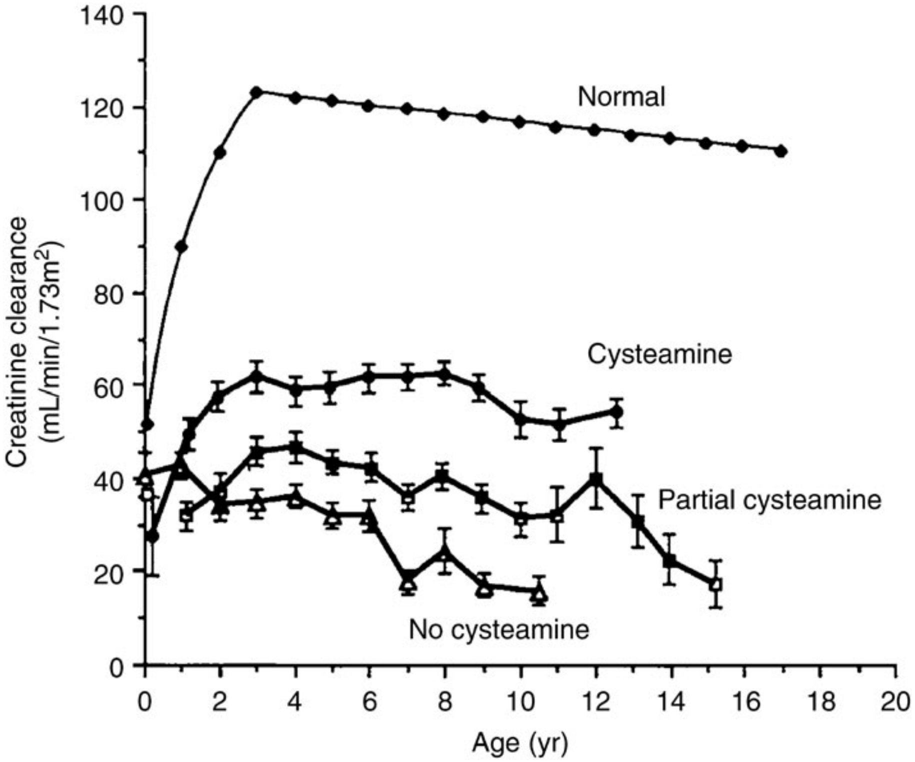

Fig. 5 *Cysteamine preserves renal glomerular function in cystinosis and allows for growth of the kidneys in the first 3 years of life*. Creatinine clearance, based upon 24-h urine collections, was used as a measure of glomerular filtration rate. The normal curve indicates rapid growth of renal function early in life as the kidneys enlarge. The other curves were constructed using values from children with cystinosis. The "No Cysteamine" curve reflects the natural history of cystinosis, i.e., a monotonic decline in creatinine clearance leading to end-stage renal disease at 10 years of age. The "Cysteamine" curve represents mean values for 17 children treated early and well with oral cysteamine. Renal growth and acquisition of increased renal function were preserved. The "Partial Cysteamine" curve was for patients treated less well, and the results fall between those in the other two groups. (Reprinted from the New England Journal of Medicine [91])

Table 1 Cysteamine therapy

	Drug	Dose	Frequency	Notes
SYSTEMIC TREATMENT ***cysteamine bitartrate***	Immediate-release (Cystagon®)	< 12 years of age: 1.30 – 1.95 g/m^2/day > 12 years of age: 2 g/day	q6h	*Start at 1/6th of the target dose and increase gradually over 6-8 weeks. Do not exceed max dose of 1.95 g/m^2/day. Monitor regularly leucocyte cystine levels. Add proton pomp inhibitor if gastric symptoms.*
	Extended-release (Procysbi®)	Start with 80% of the suggested dose for the immediate-release formulation	q12h	
OCULAR TREATMENT ***Cysteamine hydrochloride***	0.44% aqueous solution (Cystaran®)		q2h	*Ophthalmological evaluation every 6-12 months. Add artificial tears if dry cornea.*
	0.37% ophthalmic gel (Cystadrops®)		q6h	
	0.55% pharmacy-made solutions		q1h	

(Table 1). Blood levels peak at 1 h and fall off over the next few hours. Since children often have to take several pills, it is recommended to take the full dose rapidly, and the dose should be repeated if vomiting occurs within 15 min of ingestion. When initiating cysteamine therapy, dosing should begin at approximately one-sixth to one-fourth of the target dose, with incremental increases every 3–7 days. Doses are titrated to maintain leukocyte cystine levels less than 1.0–1.5 nmol half-cystine/mg protein, according to the reference value of the laboratory and the type of cells that are analyzed (i.e., whole peripheral leucocytes or granulocytes). The recommended adult dose of Cystagon® is 500 mg every 6 h, although some patients receive as much as 750 mg every 6 h. Despite its very beneficial effects on kidney function, early initiation of cysteamine therapy can delay but cannot avoid the need for kidney transplantation entirely [91]. Recent long-term registry data indicated that the overall survival of native kidney function during the last decennia was 5–10 years prolonged compared with historic cohort of patients who were not treated with cysteamine (Emma et al., unpublished data; ref. (87)). Furthermore, although cysteamine therapy can occasionally be associated with improved renal tubular function [92], the Fanconi syndrome of cystinosis is generally irreversible and refractory to cystine-depleting therapy. Some affected siblings of cystinosis patients have benefited from early diagnosis and started cysteamine before 2 months of age. In these patients, the Fanconi syndrome was delayed and attenuated but not entirely prevented. In one child identified through a neonatal screening, renal Fanconi syndrome had not developed at the age of 16 months [27].

Side effects of cysteamine preclude its use or decrease compliance to treatment in a substantial proportion of patients, especially during adolescence [42, 93]. Because cysteamine is a free thiol, it smells like rotten eggs, tastes bad, and can cause nausea and vomiting. A small fraction of cysteamine is metabolized into methanethiol and dimethylsulphide [94]. Although these metabolites are produced from less than 5% of ingested cysteamine, they are volatile, are eliminated in breath and sweat, and cause most of the bad smell that patients find offensive [94]. Breath fresheners, riboflavin, chlorophyll, and other over-the-counter remedies can help combat the foul smell. Changing clothes regularly during the hot season is also helpful. Anti-emetics can be useful for the nausea and vomiting.

Cysteamine is a potent gastric acid secretagogue; it has been used experimentally to induce duodenal ulceration in animal model. Oral cysteamine produces a fourfold increase in gastric acid production and a 50% increase in serum gastrin levels, which cause frequent gastrointestinal complaints, including nausea, dyspepsia, and epigastric pain [95]. Treatment with proton pump inhibitors is effective in reducing gastric acid hypersecretion and the risk of ulceration [95, 96]. Very rarely, patients may develop bruiselike lesions on the elbows corresponding to reactive angioendotheliomatosis on skin biopsy, striae, bone pain, and/or myalgia [97]. These lesions have been observed primarily among children on high doses of cysteamine, possibly associated with copper deficiency and interfering with collagen cross-linking [97, 98]. Other infrequent side effects include drug-induced lupus [99, 100], neutropenia, seizures, lethargy, somnolence, and drug rash [96].

Direct administration of cysteamine into the small intestine results in higher plasma cysteamine concentrations and prolonged drug exposure, compared to administration in the stomach or in the colon [101]. This allows maintenance of leucocyte cystine concentrations below trough levels for up to 12 h [102]. In 2013, an enteric-coated delayed-release (DR) formulation of cysteamine bitartrate was approved for clinical use in the USA and Europe as Procysby®. This formulation is administered every 12 h and is composed of enteric-coated capsules containing microspheronized beads that can also be pushed into feeding tubes. A phase III trial including 43 patients demonstrated noninferiority of the DR formulation in achieving leucocyte cystine depletion, compared with the standard IR formulation [103]. In addition, the trial showed that the DR formulation achieves similarly reduced leucocyte cystine levels with less cysteamine [103]. A two-year extension trial showed that mean leucocyte cystine levels remained within the therapeutic target range with stably reduced cysteamine doses [104]. Improvement in the social, school, and total function aspects of quality of life that were observed during the phase III trial persisted; kidney function and linear growth also remained stable during the two-year period [104]. Several patients treated with DR cysteamine have reported less halitosis [105]. Conversely, some patients have switched back to the IR preparation because they experienced more gastrointestinal symptoms with the DR formulation [105].

Compliance with cysteamine can be very challenging and is negatively influenced by side effects and by the frequency of administration [93, 106]. As for other chronic conditions, medication adherence often drops during adolescence; in the case of cystinosis, this generally leads to rapid deterioration of kidney function. Monitoring leukocyte cystine levels helps identify patients with poor adherence, although results reflect only short-term adherence to therapy. In this respect, serum levels of chitotriosidase, which is released as a result of macrophage activation by cystine crystals, may be more informative [107]. The clinical utility of this marker needs to be confirmed in long-term studies. Regardless of the monitoring strategy, constant patient motivation is essential. It is estimated that each year of good compliance increases kidney survival by nearly another year [108].

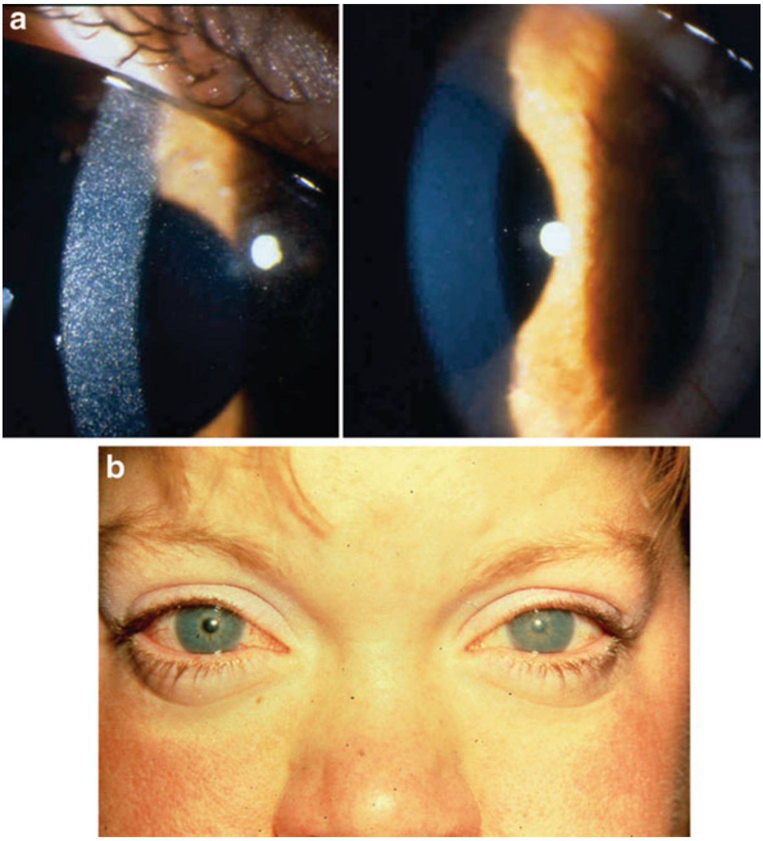
Cysteamine should not be prescribed to pregnant females because of its potential teratogenicity. Treatment should be discontinued immediately after conception and should not be resumed until after delivery. Since all reported pregnant patients were transplanted or treated with dialysis, stopping cysteamine during pregnancy has never been shown to compromise native kidney function [109]. However, cysteamine withdrawal represents a dilemma in well-treated women who reach childbearing age with preserved kidney function. For similar reasons, cysteamine is not used for prenatal treatment of affected fetuses.

Chronic oral cysteamine treatment has been shown to deplete the muscle and liver of cystine [110]. The inference that other tissues became similarly depleted is bolstered by evidence that treated patients escape the need for thyroid hormone replacement [53]. Recent evidence indicates that long-term oral cysteamine can prevent or delay most, if not all, of the late complications of cystinosis [34, 84]. Patients diagnosed with ocular cystinosis may, in fact, have a mild form of nephropathic cystinosis and may eventually develop glomerular dysfunction. Hence, such individuals should be monitored for any decline in kidney function [35].

Cysteamine Eyedrops

Oral cysteamine fails to reach the avascular cornea, so cystine crystals continue to accumulate

Fig. 6 *Corneal cystine crystals and the effects of cysteamine eyedrops*. (**a**) Left: slit lamp examination of a 21-year-old cystinosis patient showing the cornea packed with crystals. Right: Same cornea 3 years later, nearly devoid of crystals subsequent to application of topical cysteamine therapy. (**b**) An adult post-transplant female patient with cystinosis treated her right eye with cysteamine eyedrops, and the cornea became clarified. Her untreated left eye remained hazy, filled with cystine crystals



there despite cysteamine treatment. Delivery of cysteamine directly to the cornea, through cysteamine eyedrops, has proven effective. In general, ocular symptoms improve within approximately 3 weeks and the photophobia is at least partially relieved [111]. Regular application of the eyedrops can dissolve crystals in 6–12 months (Fig. 6). The beneficial effects of cysteamine eyedrops can occur at any age, and older individuals can observe clarification of the haziness in their corneas [50]. The disulfide cystamine is not as effective as the free thiol cysteamine in dissolving corneal cystine crystals [112]. Storage conditions may adversely affect the stability and efficacy of cysteamine. In many centers, hospital pharmacy–made solutions are used. These often cause discomfort related to the low pH of the solution, and are recommended to be used every hour during daytime. Most patients have difficulty in maintaining rigorous compliance. Recently, two commercial preparations have been introduced in the USA and in Europe. CYSTARAN® is a 0.44% cysteamine eyedrop solution with increased stability and tolerability [113], and CYSTADROPS® is a 0.55% viscous solution that can be applied four times per day and has shown long-term benefits on corneal crystal deposition [114, 115] (Table 1). Dry cornea is a frequent complication of ocular cystinosis; when present, artificial tears should be used in conjunction with cysteamine eyedrops. Some partial relief of corneal discomfort can be achieved by over-the-counter eyedrops, probably by virtue of their lubricating ability.

Other Therapeutic Considerations

Families must recognize that oral cysteamine therapy is lifesaving, and counseling in this regard should be part of the therapeutic plan. Vaccinations need to be handled diligently, particularly in post-transplant patients on immunosuppressive therapy.

Many children require physical, speech, and occupational therapy. By the time children with cystinosis enter school, they have interacted closely with health professionals for years and may appear sophisticated. However, they are still children who need limits as well as understanding. Conversely, some adults with cystinosis are small in stature, but should be treated as adults. Psychological help should be obtained in difficult situations.

Hematopoietic Stem Cell Transplantation

Promising results have been observed after transplantation of cystinotic knockout mice with isogenic wild-type bone marrow [116]. Despite the fact that cystinosin is a ubiquitous protein, transplanted animals showed a disproportionally high reduction in cystine content, considering the magnitude of cell engraftment, and preservation of kidney tissue damage [116]. This observation led to the discovery that hematopoietic stem cell–derived macrophages can produce tunneling nanotubes that allow transfer of cystinosin-bearing lysosomes into affected cells [117]. In addition to improving the renal phenotype of knockout animals, hematopoietic stem cells also preserved thyroid function and prevented corneal crystal formation in the same experimental model [118, 119]. In humans, the first allogenic hematopoietic stem cell transplantation was performed in a 16-year-old boy [120]. Unfortunately, the patient expired from infectious and hematological complications, but successful transfer of wild-type cystinosin and *CTNS* mRNA to the recipient cells, as well as decreased cystine crystal deposition in tissues could be demonstrated [120]. A phase I/II clinical trial (NCT03897361) to assess the safety and efficacy of gene-corrected autologous hematopoietic stem cells is underway.

Cystinosis in Adults

Table 2 Frequency of complications in 100 adults with cystinosis[a]

Finding frequency	(%)
Hypothyroidism	75
Male hypogonadism	74
Pulmonary dysfunction	69
Swallowing abnormality	60
Myopathy	50
Retinopathy	32
Vascular calcifications	31
Diabetes mellitus	24
Cerebral calcifications	22

[a] 92% of patients had received a renal allograft; many had not benefited from early treatment with cysteamine

The success of renal transplantation has created a population of adult patients with nephropathic cystinosis, and this situation has revealed the consequences of prolonged cystine accumulation [34, 121]. In untreated patients, cystinosis eventually damages or destroys nearly every tissue and organ of the body, with variable frequencies (Table 2). This multisystemic involvement presents a significant challenge to the effective transitioning of patients from pediatrics to internal medicine. The following is a description of the natural history of late cystinosis, without cystine-depleting therapy.

Growth and Appearance

Untreated or poorly treated adult cystinosis patients (males and females) average 144 cm in height (13 cm below the mean third centile for males and females) and 45 kg in weight (5 kg below the third centile for males and females) [34].

Myopathy

A large proportion of untreated adults with nephropathic cystinosis exhibit a distal vacuolar myopathy, beginning in the hands with loss of the interosseous muscles and the thenar and hypothenar eminences and progressing to the arms, legs, shoulders, neck, and chest [23, 122]. This complication does not occur before adolescence and is attributable to cystine accumulation within muscle tissue, not to carnitine deficiency, which

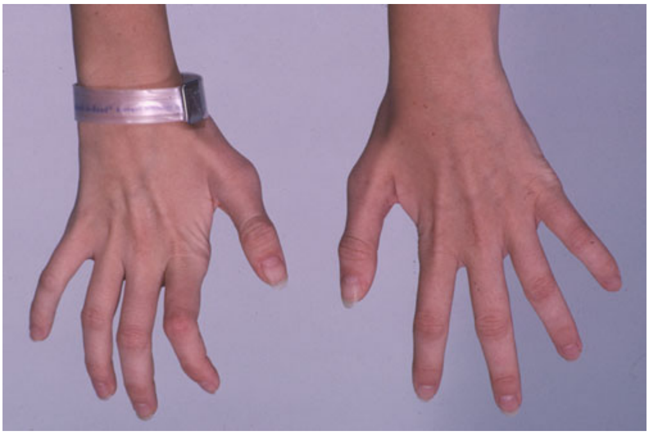


Fig. 7 *Myopathic right hand of an adult with cystinosis, untreated with oral cysteamine*. Note muscle wasting and clawhand posture of flexion

resolves with renal transplantation. Affected patients hold their fingers in partial flexion, giving the appearance of a claw hand (Fig. 7); they have difficulty opening jars. Without cysteamine treatment, the muscle weakness and atrophy progress inexorably to include the head and neck, causing poor tongue and lip strength and hypophonic speech. Nerve conduction velocities are normal, and electromyography shows a myopathic pattern [123]. Eventually, swallowing difficulty supervenes in most untreated myopathic patients. Symptoms include slow eating, choking, pain on swallowing, and heartburn [124]. The impairment results from deterioration of swallowing muscles rather than from nerve involvement, and it poses a significant risk of aspiration. The swallowing problem involves pooling in the vallecula and pyriform sinuses and, rarely, a double bolus. Other issues of oromotor dysfunction include a hyperactive gag reflex, hoarse voice, and inability to elevate the palate and move the jaw normally. Another concomitant of severe myopathy in cystinosis is restrictive lung disease with impaired respiratory function, due to weakness of the thoracic musculature rather than parenchymal lung damage [125]. Pulmonary function tests are often significantly reduced, with volumes approximating 50% of predicted for size and age. Expiratory muscle strength training programs may help to slow the progression of lung disease and decrease the risk of chronic aspiration [126]. Rickets during childhood might also confer a conical shape to the chest cavity, potentially reducing maximum achievable volumes.

Pancreatic Involvement

A significant number of post-transplant cystinosis patients have insulin-dependent diabetes mellitus [127, 128]. The frequency and severity of diabetes in cystinosis cannot be attributed entirely to the effects of steroids. Despite the fact that tacrolimus might contribute to the development of diabetes mellitus, most centers do not change their immunosuppressive regimen for cystinosis patients.

Rarely, pancreatic exocrine insufficiency has occurred in cystinosis, as evidenced by steatorrhea that is ameliorated by institution of pancreatic enzyme supplementation [129].

Hypogonadism

In the natural history of cystinosis, puberty is delayed by approximately 1–3 years, and some males never completely develop secondary sexual characteristics, including muscular development, facial hair, and a deep voice. Untreated adult male patients have low levels of testosterone and inhibin B and elevated levels of luteinizing hormone and follicle-stimulating hormone, reflecting testicular damage [130, 131]. If patients have been treated with cysteamine from early age, however, they may achieve normal sexual development and have normal sex hormone levels [131]. In most cases, sperm counts of subjects with infantile cystinosis show azoospermia, but some young patients may still have viable sperm cells in their ejaculate (unpublished data E.L.). Patients with intermediate or ocular cystinosis have oligospermia or normospermia, and can induce pregnancies (unpublished data E.L.). To date, one male patient with infantile cystinosis has fathered twins after testicular sperm aspiration combined with intracytoplasmic sperm injection [132]. Female patients have no apparent impairment of ovulatory function and have normal sex hormone levels. Several women with cystinosis have given birth to normal children [109]. Similar to other women with a kidney transplant or with chronic kidney failure, their pregnancy should be considered high risk and monitored carefully in specialized centers. As mentioned above, oral cysteamine therapy should be discontinued until after delivery.

Central Nervous System Involvement

Brain cystine levels were originally considered normal in cystinosis, and the brain was thought to be spared. This notion was discarded, however, as patients survived to adulthood by virtue of renal replacement therapy. In fact, many untreated adults with cystinosis have cerebral atrophy and periventricular and basal ganglia calcifications on CT scans [133]. These findings have not correlated directly or immediately with functional deficits. Reported neurological symptoms include seizures, memory and cognitive defects, stroke episodes, inability to walk, and loss of speech [134–137].

Ocular Findings

Untreated corneas of cystinosis patients continue to accumulate crystals and can develop a vision-impairing band keratopathy. Chronic photophobia can result in irreversible blepharospasm and posterior synechiae (scar tissue binding the iris to the posterior lens), impairing accommodation and causing angle closure glaucoma [21, 138]. Loss of retinal pigment epithelium can damage the rods and cones, initially impairing night and color vision and eventually reducing visual acuity. The retinopathy can be confirmed by electroretinography [139]. An estimated 3–5% of adults who have not received oral cysteamine therapy have retinal blindness.

Other Complications

Vascular calcifications occur with increased frequency among all individuals who have received dialysis, but the prevalence among cystinosis patients appears greater than expected [140]. Two young men with cystinosis died of severe liver dysfunction with portal hypertension; the pathologic diagnosis was nodular regenerating hyperplasia [25].

Death

In a study of 100 adults aged 18–45 years seen at the NIH Clinical Center between 1985 and 2006, 33 had died at an average age of 28.5 years [34]. In a second French study of 86 patients at least 15 years of age diagnosed between 1961 and 1995, 24 patients died at a mean age of 26.8 years. In both studies, lack of treatment with cysteamine was the major risk factor for early death.

Abstract

The kidneys are tasked to maintain homeostasis, and acid-base balance is a key part of this. They accomplish this task with nanomolar precision, as blood pH is maintained in a very tight range of 7.37–7.43, equivalent to a proton concentration around 40 nmol/l. As our diet typically presents an acid load, the equivalent of this load must be excreted in the urine to maintain balance. In addition, the formation of hydroxyapatite, an alkali needed for bone mineralization, generates an additional acid load that must be excreted by the kidneys. Together, these processes generate an acid load of typically 1–3 mmol/kg/day. Yet, before acid excretion can be accomplished, the kidney tubules must reclaim virtually all of the filtered bicarbonate, approximately 4000 mmol/day in an adult, as in the acid-base balance each molecule of bicarbonate lost is equivalent to one proton gained.

Reclaiming of filtered bicarbonate occurs predominantly in the proximal tubule, whereas protons are secreted in the distal tubule. Each of these processes involves a number of specialized enzymes and transport molecules, dysfunction of which can lead to renal tubular acidosis (RTA). Defects in bicarbonate reabsorption consequently are termed proximal RTA, whereas defects in proton secretion cause distal RTA. And while proximal RTA is difficult to treat, as, like in any tubular wasting disorder, supplementation primarily increases tubular losses, distal RTA can be treated relatively easy by providing alkali supplementation in an amount matching the acid load. In this chapter, we discuss the molecular basis of renal acid-base homeostasis, the different forms and etiologies of renal tubular acidosis, and their diagnosis and management.

Introduction

Renal tubular acidosis (RTA) is defined as a group of tubular transport disorders affecting the reabsorption of bicarbonate (HCO_3^-), secretion of hydrogen ion (H^+), or both in the absence of a substantial impairment in the glomerular filtration rate [1]. The resultant biochemical abnormalities are characterized by a hyperchloremic/normal anion gap metabolic acidosis.

Clinical consequences of the acidosis include bone disease, such as rickets or osteomalacia due to buffering of acid by hydroxyapatite in the bone [2]. The excess calcium dissolved from the bone is excreted in the urine which can result in nephrocalcinosis and/or urolithiasis [3]. In children, growth failure is a common presentation [4].

RTA can be inherited (primary) or acquired (secondary). In this chapter, we review the various forms of RTA, the history, molecular basis, and the treatment.

Historical Development of the Classification of RTA

The study and understanding of the renal tubular acidosis began in the early twentieth century and has continued to evolve in the twenty-first century with the expansion of molecular biology.

In a British Paediatric Association meeting of 1935, Lightwood first described a group of six young children (from a large autopsy series) with what he described as “calcium infarction” of the kidneys [5]. This was later recognized as the first report of infants with nephrocalcinosis from renal tubular acidosis. Only a year later, Butler and colleagues described four infants with similar features and hyperchloremic acidosis, although the connection between acidosis and nephrocalcinosis was at that time unclear [6]. A decade later, Albright brilliantly provided what is considered the first pathophysiological description of RTA [7]. Key insights provided by Albright in his extensive essay on "osteomalacia and late rickets" included: a) an understanding of the disease as "renal acidosis resulting from tubular insufficiency without glomerular insufficiency," b) the understanding that acidosis causes hypercalciuria, c) the consequent link to nephrocalcinosis/urolithiasis, d) a correlation between this "renal tubular insufficiency" and the previously described familial periodic paralysis, and e) the treatment recommendation of these patients with a solution of sodium citrate previously designed by Alfred Shohl.

The term "renal tubular acidosis" was coined in 1951 [8].

During the following years, further research on the physiology of renal tubular acidification led to the development of different techniques to measure the capacity of the distal tubules for acid secretion. This identified "distal tubular insufficiency" as the main mechanism for the disease. In particular, the work of Wrong and Davies not only outlined what later on became the gold standard diagnostic protocol (ammonium chloride test), but also provided an extended phenotype with the description of the so-called incomplete renal tubular acidosis, defined as a failure to acidify urine in response to an oral acid load but with an absence of overt systemic acidosis in routine conditions [9].

Stapleton and colleagues in 1949 described patients with significant bicarbonaturia in a context of low serum bicarbonate [10]. This suggested that in some patients the disease mechanism was not impaired distal acidification but rather proximal reabsorption. Rodriguez-Soriano and Edelman subsequently proposed a new classification, based on the threshold for bicarbonate excretion and thereby distinguishing between proximal and distal RTA [1]. Later on, Morris and colleagues described another subtype, denominated type III, and characterized by a combination of proximal and distal RTA [11]. This was based on observations in two infants and most likely reflected the transient proximal tubular dysfunction commonly seen in patients with distal RTA at presentation, which resolves with treatment [4]. However, in the 1980s, a rare autosomal recessive syndrome presenting with osteopetrosis, combined proximal and distal renal tubular acidosis, cerebral calcification, and mental impairment was described and linked to pathogenic variants in *CA2*, encoding carbonic anhydrase type II, expressed both in proximal and distal segments and involved in bicarbonate reabsorption, as well as proton secretion [12].

The discovery of aldosterone did not only have a significant impact on our understanding of sodium and potassium physiology but also subsequently led to the recognition of a fourth type of renal tubular acidosis. This form was seen in patients with aldosterone insufficiency or resistance and is characterized by hyperkalemia rather than hypokalemia [13]. This form of RTA was then referred to as type IV RTA. It is important to recognize, however, that the primary defect here is a failure to reabsorb sodium in the collecting duct with the resultant "voltage defect" impairing acid secretion [14]. Thus, type IV RTA is primarily a salt-wasting disorder with a secondary defect in distal acidification.

Over the past century, advances in renal physiology, clinical investigations, and molecular genetics have greatly improved our understanding of the various forms of renal tubular acidosis. Currently, the diagnosis and classification of the various types of renal tubular acidosis continue to rely on biochemical measurements of blood and urine but are increasingly complemented by genetic testing.

Currently, more than 50 disease genes for kidney tubulopathies are recognized, and the list keeps on expanding. Because of the specific phenotype associated with mutations in most genes, an accurate clinical diagnosis can usually be established. However, even in expert centers, genetic testing can sometimes further specify or even correct the clinical diagnosis, so that genetic confirmation is usually recommended because of potentially important implications not only for genetic counseling, but also for treatment [15, 16].

Physiology of Acid Secretion

Extracellular pH is normally regulated within an extremely tight range (7.37–7.43), reflecting nanomolar changes in proton concentration. As protons can bind to amino acids like histidine, a change in pH will lead to a change in the charge of a given protein, which in turn can affect protein folding and function [17]. This highlights the critical importance of acid-base homeostasis for cellular function in general, and many of the non-specific clinical symptoms encountered in untreated patients with distal renal tubular acidosis such as fatigue and lack of appetite may reflect this.

A common western diet is usually generating a daily acid load of 1 mmol/kg of body weight [18], and growing children typically produce an extra 1–2 mmol/kg of body weight as a result of bone mineralization (generation of hydroxyapatite), which in total makes an approximate acid gain of 2–3 mmol/kg/day that the kidneys need to excrete [19, 20]. If the kidneys are not capable of eliminating this acid load, the body will need to use its existing buffers in order to neutralize the excess (bicarbonate, hemoglobin, phosphate, and other plasma proteins). The amount of acid excreted by the kidneys is referred to as net acid excretion (NAE) and is expressed quantitatively as:

$$NAE = \left(U_{NH_4} + U_{TA} - U_{HCO_3}\right) \times V$$

where V is the urinary flow rate, U_{NH4} is the urinary ammonium concentration, U_{TA} is the urine titratable acid concentration, and U_{HCO3} is the urinary bicarbonate concentration. Thus, the components of tubular acid-base homeostasis can be thought of as bicarbonate reclamation (fundamentally happening in the proximal convoluted tubule), as well as ammonium and titratable acid excretion (primarily taking place in the distal nephron) [5, 21].

HCO_3^- Reabsorption

One of the main functions of the kidneys is the excretion of waste products. To this end, our kidneys maintain a high glomerular filtration of about 150–180 l per day in a healthy adult. As bicarbonate is freely filtered in the glomerulus, approximately 4000 mmol/day of it must be reabsorbed by the tubules to prevent excessive loss of alkali and subsequent acidosis. Different transporters and enzymes in the proximal tubule work together to reabsorb approximately 80% of the filtered bicarbonate in this segment [22].

The mechanisms for proximal reabsorption are shown in Fig. 1. The two main transport processes in this segment are H^+ secretion at the luminal membrane, via a specific Na^+/H^+ exchanger (NHE3/SLC9A3) and HCO_3^- transport at the basolateral membrane via a Na^+/HCO_3^- cotransporter (NBC1/SLC4A4), while both processes are supported by the activity of two different isoforms of the enzyme carbonic anhydrase (CA II and IV) [23].

NHE3 provides roughly 65% of apical proton secretion [24]. Transport is electroneutral, driven by a lumen-to-cell Na^+ gradient (maintained by the basolateral Na^+/K^+ ATPase), stimulated by intracellular acidosis, and inhibited by high concentrations of amiloride [23]. The remaining third of the proton secretory rate is provided by a H^+-ATPase located in the luminal membrane which derives its energy directly from ATP [24].

Once the hydrogen ion is in the lumen of the proximal convoluted tubule, it combines with bicarbonate to form carbonic acid (H_2CO_3), which will then form carbon dioxide and water. The enzyme carbonic anhydrase is critical for catalyzing this process [25]. One isoform of this enzyme (CA IV) is located in the brush border membrane of the proximal tubule and serves to catalyze the hydrolysis of carbonic acid into H_2O and CO_2 (the latter diffusing through the apical membrane back to the cytosol) while another isoform of the enzyme (CA II) is cytosolic and catalyzes the reverse reaction, so that the resulting proton can be secreted into the lumen and bicarbonate reclaimed across the basolateral membrane [26].

Fig. 1 Model of bicarbonate reabsorption by a proximal tubule cell. The Na–K–ATPase located in the basolateral membrane generates and maintains the low intracellular sodium concentration. Protons are excreted into the tubule lumen by the sodium-proton exchanger (NHE3) where they combine with bicarbonate to form carbonic acid. In the presence of carbonic anhydrase IV (CAIV), the carbonic acid is hydrolyzed to water and carbon dioxide which enter the cell and recombine to form carbonic acid by the action of intracellular carbonic acid II (CAII). The carbonic acid ionizes into a proton which is then excreted into the lumen and bicarbonate which is transported by the sodium bicarbonate symporter (NBC1) into the bloodstream. (Reprinted with permission from Fry and Karet [157])

One of the particular characteristics of bicarbonate reabsorption within the proximal tubule is that its transport is saturable [27], which implies that in conditions of rising blood bicarbonate the filtered load of bicarbonate can potentially exceed the kidney's reabsorption rate and therefore bicarbonate will be lost in the urine. Studies in humans with normal proximal tubular function have provided evidence for such physiological titration curves [27].

In addition, about 20% of filtered bicarbonate is reabsorbed by passive back-diffusion along the paracellular pathway. Overall, proximal bicarbonate reabsorption is influenced by a number of factors, including luminal bicarbonate concentration and flow rate, extracellular fluid volume, peritubular bicarbonate concentration, and pCO_2, Cl^-, K^+, Ca^{2+}, phosphate, parathyroid hormone, glucocorticoids, α-adrenergic tone, and angiotensin II [28].

The thick ascending limb of Henle's loop reabsorbs about 15% of the filtered bicarbonate load by a mechanism similar to that present in the proximal tubule, i.e., through Na^+/H^+ apical exchange.

Ammonia Generation and Recycling

The generation of ammonia (NH_3) plays an essential role in the maintenance of the acid-base balance by the proximal tubule, and this is mainly the case due to its capacity to buffer hydrogen ions [29]. The importance of this becomes apparent, when considering the acid load in concentration terms: If the minimal urine pH is 5, this is equivalent to a H^+ concentration of 10 μmol/l. Thus, an acid load of 100 mmol unbuffered H^+ would require a minimal volume of urine of 10,000 liters for excretion!

The high pKa (~ 9.0) of the reaction $NH_3 + H^{+-} \rightarrow NH_4^+$ implies that within an average urinary pH of 7.0, virtually all of the ammonia (NH_3) in the urine will be present as ammonium (NH_4^+), hence limiting the amount of free hydrogen ions in the urine and making the ammonium excretion rate a quantitatively more important factor for the excretion of acid than urinary pH.

Ammonia is generated in the proximal tubule. The metabolism of glutamine provides two molecules of NH_3, secreted into the tubular lumen mainly as NH_4^+, and two of HCO_3^- which are subsequently transported to the basolateral membrane. Half of the produced ammonia is excreted in the urine, and the other half accesses the systemic circulation in order to produce urea in the liver (an event that requires consumption of HCO_3^-, and therefore the net effect on acid-base balance is neutral under physiological circumstances).

The proportional relationship between excreted and retained ammonia is modified by acidosis, and in consequence, urinary ammonia can transiently exceed ammoniagenesis [30]. The ability of the neonatal kidney to upregulate ammonium excretion is somewhat limited and can prolong the recovery phase of acidosis in infants. The upregulation of ammonium production and secretion serves as the principal means of correcting acidosis that is due to nonrenal causes. Indeed, the inability of the kidney to secrete acid as ammonium is a key feature of distal RTA.

Ammonia is electroneutral and can diffuse across membranes. In contrast, ammonium is a cation and thus membrane impermeable, but the ionic radius is similar to potassium, and therefore ammonium can substitute for potassium on many potassium transporters. The difference in membrane permeability between ammonia and ammonium causes a phenomenon called "ammonia trapping," where binding of ammonia to protons in the tubular lumen "traps" it there.

In the proximal tubule, NH_4^+ is secreted into the tubular lumen by NHE3/SLC9A3 (sodium hydrogen exchanger 3) and also by ammonia trapping. In the thick ascending limb of the loop of Henle, NH_4^+ is then reabsorbed predominantly by NKCC2/SLC12A1, diffusing across the basolateral membrane as NH_3 and also transported via a sodium and NH_4^+ exchanger NH4 [31]. An overview of ammonia transport is given in Fig. 2.

Finally, in the collecting duct, ammonia is trapped again in the tubular lumen by proton secretion [32]. The transport of NH_3 through the basolateral membrane in this segment is further facilitated by the ammonia-specific transporters Rhesus glycoproteins Rhbg and Rhcg and also the Na/K-ATPase. Cytosolic NH_3 is transported across the apical membrane by a combination of Rhcg and diffusion, while apical H^+ secretion involves both H^+-ATPase and H^+-K^+-ATPase [33].

Distal Tubular H^+ Secretion

In the distal nephron segments, urinary acidification is achieved via three related processes [23]:

1. Reabsorption of the small fraction of filtered HCO_3 that escaped previous segments (~10–20%)

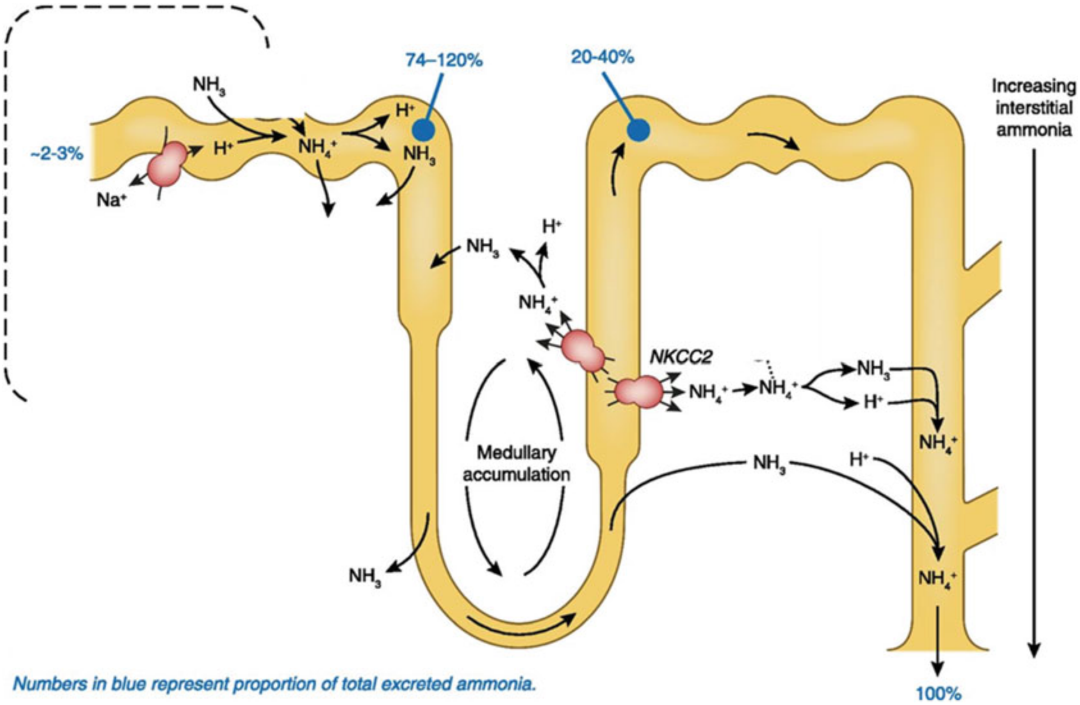

Fig. 2 Overview of renal ammonia transport. Renal ammoniagenesis occurs primarily in the proximal tubule from glutamine metabolism, forming ammonium and bicarbonate. There is apical NH_4^+ secretion involving NHE3 and parallel H^+ and NH_3 transport. Ammonia reabsorption in the thick ascending limb occurs via apical NKCC2-mediated uptake and results in medullary ammonia accumulation. Ammonia is secreted in the collecting duct via parallel H^+ and NH_3 secretion. Ammonia (NH_3) is "trapped" in the tubular lumen by binding to H^+, forming ammonium (NH_4^+). The numbers in blue represent the proportion of total excreted ammonia. (Modified from [158])

2. Titration of divalent basic phosphate (HPO_4^{2-}), which is converted to the monovalent acid form ($H_2PO_4^-$)
3. Luminal accumulation of ammonia (NH_3), which buffers H^+ to form nondiffusible ammonium (NH_4^+)

The collecting duct contains three different epithelial cell types: the principal cells and the intercalated α- and β-cells. Secretion of protons occurs via a vacuolar H^+-ATPase expressed in the apical membrane of α-intercalated cells [34, 35]. Bicarbonate generated in this process is exchanged for chloride ions at the opposite pole of the cell (basolateral membrane) via the anion exchanger AE1/SLC4A1 [36]. Chloride can then exit the α-intercalated cell through the apical membrane via the potassium chloride cotransporter (KCC) or the chloride channel, CLCNKB [37, 38]. Lastly, carbonic anhydrase (CA) isoenzymes II (cytosolic) and IV (luminal side of the plasmatic membrane) play a critical role in catalyzing the production of proton and bicarbonate ions intracellularly, but also the breaking down of carbonic acid into water and CO_2 in the tubular lumen, with CO_2 diffusing back into the cells allowing the regeneration of bicarbonate [25].

The β-intercalated cells are characterized by an inverted polarity of transporters compared to the α- cells and so extrude bicarbonate into the tubular lumen rather than protons. The apical Cl^-/HCO_3^-exchanger, Pendrin (SLC26A4), is expressed in the apical membrane; HCO_3^- is secreted into the luminal space while both ATPases, the H^+-pump and the H^+/K^+ exchanger, are present in the basolateral membrane. Thus, β-intercalated cell activity is important for correcting metabolic alkalosis.

The principal cells of the collecting duct are responsible for the reabsorption of sodium and the secretion of potassium and do not directly secrete protons into the tubular fluid. Their activity however influences the rate of acid secretion indirectly, by affecting the electrical potential difference across the epithelium. This is the reason why factors (disease or drugs) with primary effect on sodium/potassium transport in the collecting duct can disturb acid-base balance [39]. Distal urinary acidification is influenced by multiple factors, including blood pH and pCO_2, distal sodium transport and transepithelial potential difference, aldosterone, and potassium [23].

Besides ammonia, urinary protons can also be buffered by titratable acids, which include phosphate, sulfate, and other anions. From these, phosphate is quantitively the most important. Inorganic phosphate can be found in the blood as different ionic species (H_3PO_4, $H_2PO_4^-$, HPO_4^{2-}, and PO_4^{3-}), with $H_2PO_4^-$ and HPO_4^{2-} being the most abundant at physiological values of pH. The pK for the equilibrium between $H_2PO_4^-$ and HPO_4^{2-} is ~6.8. Therefore, at an average blood pH of 7.4, the $[H_2PO_4^-]/[HPO_4^{2-}]$ ratio is approximately 4:1. While urine is flowing through the collecting duct where the pH is lower, HPO_4^{2-} tends to accept protons, becoming $H_2PO_4^-$, and therefore participates in acid buffering [39].

Proximal Renal Tubular Acidosis

Proximal RTA (pRTA) refers to the impaired ability of the proximal tubule to reabsorb bicarbonate and generate ammonia.

Pathophysiology

Bicarbonate reabsorption in the proximal tubule is a saturable process (see above). The threshold for bicarbonate reabsorption will be the main determinant of the blood bicarbonate concentration and is normally around 24–26 mmol/L. If the bicarbonate concentration in blood exceeds this threshold, transport will be saturated, and bicarbonate will start to be excreted in the urine, bringing the blood levels down until it matches the threshold, and then all of the filtered bicarbonate will be reabsorbed again.

pRTA is mainly characterized by a reduced threshold for the reabsorption of bicarbonate [40]. Typically patients with pRTA tend to have thresholds around 14–18 mEq/L [41]. It is this reduction in the capacity for reabsorption of bicarbonate that makes the treatment of patients with pRTA particularly challenging: As the patient is treated with bicarbonate and the blood bicarbonate rises, bicarbonaturia will increase, limiting the increase in the blood bicarbonate concentration [42].

Hypokalemia is a common finding in patients with pRTA and likely relates to impaired proximal potassium reabsorption (in generalized proximal dysfunction), and also from volume depletion and increased serum aldosterone concentration, as NHE3-mediated bicarbonate recovery is also a key pathway for proximal sodium reabsorption [43].

Although treating these patients can be particularly challenging, their acidemia is only moderate. Having a stable tubular reabsorption threshold means that all filtered bicarbonate can be reabsorbed once the serum levels match the threshold [44, 45]. Therefore, the serum bicarbonate concentration will not fall below this threshold, which is usually about 14–16 mmol/L. Notably, distal tubular acidification is intact, and the urinary pH can fall below 5.3 in proximal RTA. Thus, when the serum bicarbonate is below the tubular reabsorption threshold, the distal tubule can excrete the daily acid load and maintain acid-base balance. This is reflected in normal calcium excretion rates and the absence of rickets or osteomalacia in patients with isolated pRTA, although short stature is a common finding [44].

Renal Fanconi Syndrome

Besides reabsorbing the bulk of filtered water and solutes, the proximal tubule is also the sole nephron segment responsible for the reabsorption of low-molecular weight proteins (LMWP), glucose, amino acids, and phosphate. A generalized failure of the proximal tubule is referred to as renal Fanconi syndrome (RFS) and is characterized by a typical biochemical “fingerprint,” which includes hypokalemic metabolic acidosis with hypophosphatemia and elevated excretion of glucose, phosphate, LMWP, and aminoacids in the urine.

PRTA almost invariably occurs in the context of RFS, which is discussed in Chap. “Fanconi Syndrome. Renal Tubular Disorders.” In contrast, isolated pRTA is exceedingly rare.

Etiology

Hereditary Isolated pRTA

Inherited pRTA has been described with autosomal dominant and autosomal recessive patterns of inheritance.

Autosomal recessive inheritance in isolated pRTA has been linked to variants in *SLC4A4*, encoding the basolateral Na^+/HCO_3^- exchanger [46, 47]. Besides pRTA, these patients have prominent eye abnormalities, such as band keratopathy. So far, only very few cases have been described in the literature, reflecting the extreme rarity of this disorder [48–50].

PRTA with autosomal dominant inheritance pattern also appears to be very rare and has so far been reported in only two families [44, 46]. Yet, despite the first family being reported already in 1977, attempts at identification of the underlying genetic problem have so far been unsuccessful.

Diagnosis

The formal diagnosis of pRTA requires the demonstration of urinary bicarbonate wastage with systemic acidosis [51]. Traditionally, a fractional bicarbonate excretion of $\geq 15\%$ is said to be needed to establish the diagnosis of pRTA [52]. Given the capacity of the distal nephron to reabsorb bicarbonate, however, even mild bicarbonate wastage (fractional excretion $\sim 5\%$) could be sufficient for the diagnosis. The most definitive way to diagnose pRTA is to assess bicarbonate excretion when blood bicarbonate is increased by administration of sodium bicarbonate (HCO_3^-titration test). When pRTA is present, a marked increase in urinary bicarbonate excretion and urine pH occurs as blood bicarbonate rises above the renal threshold, whereas bicarbonate excretion decreases and the urine pH falls when blood bicarbonate is reduced [51].

Such formal tests for bicarbonate excretion are however rarely performed in clinical practice, and attention to a few clinical features is usually sufficient to distinguish pRTA from the distal form [53, 54]:

1. Concomitant presence of glycosuria, aminoaciduria, hyperphosphaturia, and LMWP excretion suggesting RFS or, alternatively, of the typical eye findings suggesting SLC4A4-related disease.
2. Intact ability to lower urine pH <5.3 when the blood bicarbonate is lower than the renal threshold for bicarbonate reabsorption (i.e., without bicarbonate supplementation).
3. Urinary anion gap is normal/negative (while in distal RTA it is consistently positive).
4. Skeletal abnormalities and rickets are less common compared to distal RTA.
5. Nephrocalcinosis and urolithiasis are rare.

Treatment

Patients with inherited and acquired pRTA are usually given alkali supplements [42]. Particularly in children, alkali replacement may be helpful to support growth [55]. Unfortunately, as soon as blood bicarbonate levels exceed the threshold of reabsorption in the proximal tubule, the excess bicarbonate is lost in the urine. Consequently, the higher the dose, the more is lost in the urine, and prescribed doses as high as 15 mEq/kg/day have been reported [51]. Bicarbonate loss in the urine is most pronounced if supplementation is given in infrequent large doses: After each dose, blood bicarbonate will briefly rise, leading to exaggerated losses until the blood concentration has decreased again to the threshold level. For this reason, supplementation should be sustained over as long a time as possible to avoid such brief peaks in serum levels with consequent large increases in urinary losses.

Some authors also recommend the concomitant use of a thiazide diuretic in order to reduce bicarbonate losses. The principle behind this idea is to enhance proximal tubule and loop bicarbonate reabsorption by inducing a contraction of the extracellular volume [56]. However, the addition of a thiazide can aggravate hypokalemia by promoting potassium excretion. Moreover, the loss of sodium bicarbonate in itself causes volume contraction, further compounded by thiazides, and for these reasons this therapy should be carefully considered and monitored.

Distal Renal Tubular Acidosis (Type I)

Distal RTA (dRTA) refers to the impaired ability of the distal tubule to secrete protons.

Pathophysiology

As initially defined in 1967 [57], distal renal tubular acidosis describes the impaired ability of the kidney to maximally decrease the urine pH under conditions of systemic acidosis. The molecular mechanisms (Fig. 3) underlying this process were discovered at the end of the twentieth century by a combination of physiologic studies, molecular cloning, and genetic investigations in inherited forms of dRTA [58]. This secretion should match the daily acid load to maintain overall acid-base balance. A common western diet generates a daily acid load of 1 mmol/kg of body weight [18], and children typically produce an extra 1–2 mmol/kg of body weight for bone mineralization (formation of hydroxyapatite), generating approximately 2–3 mmol/kg/day that the kidneys need to excrete [19, 20].

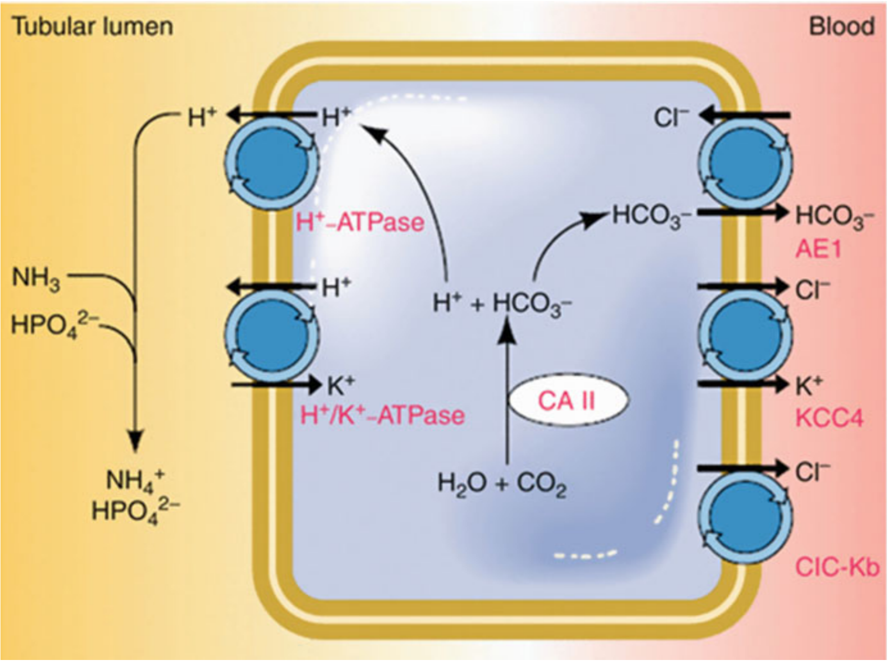

Fig. 3 Model of acid excretion in an alpha-intercalated cell in the distal nephrons. Protons are excreted into the tubule lumen by the proton ATPase and are buffered by ammonia or titratable acid (mostly phosphate). Inside the cell, carbonic anhydrase II (CAII) provides the protons and bicarbonate through the hydration of carbon dioxide to form carbonic acid. Bicarbonate is excreted into the bloodstream by the action of the chloride bicarbonate exchanger (AE1) on the basolateral membrane. Chloride homeostasis is maintained by the potassium chloride cotransporter (KCC4) and the chloride channel (ClC-Kb). (Reprinted with permission from Fry and Karet [157])

Pathophysiological Consequences

The distal inability to excrete excess body acid will cause a progressive acidosis with increase of the base deficit. Pathophysiologic consequences include nausea, vomiting, fatigue, tachypnea, mineral bone disease, hypercalciuria, salt wasting, hypocitraturia, nephrocalcinosis/urolithiasis, and also proximal tubular dysfunction [59–62].

Bone Disease

At the extracellular level, bicarbonate is consumed due to its buffering action, and once depleted, other buffers start to take over. The most abundant is phosphate, which is stored predominantly in the skeleton in the form of hydroxyapatite [$Ca_5(PO_4)3$ (OH)]. Hydroxyapatite dissolves in an acidic environment, releasing not only hydroxyl ions (OH^-), but also calcium which subsequently must be excreted in the urine, leading to hypercalciuria and calcification (nephrocalcinosis/urolithiasis). Thus, patients with untreated dRTA have a negative calcium balance [1].

In children, the clinical consequence of this is the development of rickets, while in adults it is osteomalacia [7]. The exact physiopathological mechanisms linking mineral bone disease with systemic acidosis are yet to be elucidated. In vitro studies using rat cells suggest that acidosis does not directly affect the composition of the mineral osteoid but stimulates the resorptive activity of the osteoclasts by directly activating the cells [63] and also inhibiting the synthetic function of osteoblasts [64]. In contrast, data from bone biopsies in patients with dRTA showed suppressed activity of both osteoblast and osteoclasts with low turnover bone disease and reduced mineral density [65]. Importantly, these findings are reversible with treatment of the acidosis [66].

Hypercalciuria and Nephrocalcinosis

Not only hypercalciuria contributes to the risk of nephrocalcinosis, but also the increased proximal reabsorption of citrate with subsequent hypocitraturia. Citrate is the most important and abundant organic urinary base and also the most important chelator for calcium in the urine. It is an antilithogenic agent by preventing calcium binding to oxalate or phosphate with consequent precipitation. The reabsorption of citrate happens exclusively in the proximal tubule through a specific cotransporter (sodium-dicarboxylic acids) NaDC1/SLC13A2 which shows increased expression in the apical membrane during systemic acidosis [67, 68]. Once citrate is taken up by the proximal tubular epithelial cell, it is metabolized by the mitochondria through the citric acid cycle, generating CO_2 and H_2O while consuming two or three protons (H^+). This suggests that a normally functioning proximal tubule is needed to develop hypocitraturia and may explain why nephrocalcinosis and hypocitraturia are typical in distal RTA and not in proximal RTA or the renal Fanconi syndrome.

Nephrocalcinosis in itself can have a negative impact on patients' prognosis with studies suggesting that it may accelerate loss of kidney function by triggering a local inflammatory response [69, 70]. It also may impair the urinary concentration ability, presumably due to interstitial calcification [71]. Nephrocalcinosis has also been associated with erythrocytosis, presumably reflecting impaired interstitial perfusion [72, 73]. Importantly, nephrocalcinosis in itself can be associated with dRTA, suggesting that it can be a cause as well as a consequence of dRTA.

Urolithiasis shares the same pathophysiological mechanisms with nephrocalcinosis and as such is common in patients with dRTA, with selected series from tertiary centers showing a prevalence as high as 77% in primary dRTA, and this seems to be also true for secondary forms [74, 75]. The combination of hypocitraturia, hypercalciuria, and a high urinary pH creates a favorable environment for calcium-phosphate precipitation, and brushite is the predominant mineral found in urinary stones from patients with dRTA. However, other stone compositions are also seen, including struvite, calcium oxalate, purines, and mixed stones perhaps reflecting the particularities of each individual and their respective stone formation risk: recurrent urinary tract infections, the degree of urinary acidification impairment, diet, and other comorbidities [74].

Hypokalemia

Hypokalemia, although variable, is another classical finding in patients with dRTA [76, 77]. The exact mechanisms involved in potassium wasting have not been fully elucidated but likely include a combination of different factors. Failure of distal acid secretion leads to an electrochemical gradient that favors potassium secretion. Renal potassium wasting through compensatory overactivity of the H^+/K^+-ATPase in the collecting tubule has also been proposed [76]. In addition, impaired urinary concentrating ability and subsequent increased urinary flow rate activate K-secretion via BK-channels [31]. Finally, hyperaldosteronism [77] related to volume contraction has been documented and may contribute to further urinary potassium wasting.

Hypokalemia can be very severe, causing rhabdomyolysis [78] and muscle paralysis, which can be one of the presenting signs of dRTA [79]. In a report describing 14 patients with hypokalemic rhabdomyolysis, 7 patients had an underlying diagnosis of dRTA [78].

Salt Wasting

Not only potassium wasting is a feature of dRTA, but sodium reabsorption can be also impaired, likely due to impaired exchange with protons. But also acidosis per se may cause decreased sodium reabsorption as the abnormally low pH can affect the normal functioning of several transporters [80].

Impaired Ammonia Excretion

Ammonium excretion accounts for the majority of basal bicarbonate generation, and changes in its excretion rate are the primary response to acid-base disorders (see also “ammonia generation” above) [31].

The failure to “trap” ammonia in the tubular lumen via H^+ secretion is associated with impaired ammonia excretion [80]. Indeed, hyperammonemia has been reported as one of the presenting features in patients with distal renal tubular acidosis particularly during severe acidotic episodes [81]. It may be more common than reported, as ammonia is not routinely measured in clinical practice.

From a small selected Japanese cohort of 11 patients with pathogenic variants in subunits of the proton pump, approximately one-third [4] were found to have raised levels of ammonia in the blood at presentation [82]. However, to what degree these raised ammonia levels reflect insufficient excretion versus an acidosis-associated defect in metabolization is unclear. The fact that the levels are only reported to be raised during severe acidosis argues for the latter, as impaired ammonia trapping is a permanent feature of dRTA.

Etiology/Genetics

So far, five different genes have been found to cause inherited distal RTA (see Table 1).

Very recently, a single patient with an unusual phenotype of acidosis and end-stage kidney disease with death in infancy was described with a homozygous variant in a nonpreviously disease associated subunit (*ATP6V1C2*) of the H^+-ATPase pump [88]. However, until further patients are identified, *ATP6V1C2* remains a gene of uncertain significance with respect to distal renal tubular acidosis [89].

Table 1 Genes associated with dRTA listed are currently recognized genes associated with dRTA. AD, autosomal dominant; AR, autosomal recessive; SND, sensorineural deafness; AI, amelogenesis imperfecta; N/A, not available

Gene	Function	Phenotype MIM	Inheritance	Extrarenal features	References
SLC4A1	Anion exchanger (AE1)	179,800	AD, AR	Occasionally hemoglobinopathy	[83]
ATP6V1B1	V-type H^+ ATPase subunit B1	267,300	AR	SND	[84]
ATP6V0A4	V-type H^+ ATPase subunit a4	602,722	AR	+/−SND	[85]
FOXI1	Transcription factor FOXI1	N/A	AR	SND	[86]
WDR72	WD repeat-containing protein 72	N/A	AR	AI	[87]

Genotype-Phenotype Correlation

Sensorineural Deafness

Additional clinical features can be helpful to pinpoint the underlying genetic cause. As the vacuolar proton pump is also expressed in the inner ear, patients with dRTA associated with ATP6V1B1, FOXI1, and to a lesser degree, ATP6V0A4 typically have sensorineural hearing loss. FOXI1 is a transcription factor controlling expression of several genes involved in acid secretion, including subunits of the proton pump, and as such it does share a similar phenotype.

Hemoglobinopathy

Patients with AR mutations in anion exchanger 1, typically from Southeast Asian ethnic background, can have concomitant ovalocytosis or spherocytosis (see section "SLC4A1," below).

Amelogenesis Imperfecta

WDR72 was initially described as a disease gene for amelogenesis imperfecta, a congenital enamel defect [90]. Indeed, the presenting symptom in some patients with *WDR72*-associated dRTA was amelogenesis imperfecta, with dRTA only noted by "reverse phenotyping," i.e., further investigations prompted by the genetic result.

Molecular Aspects of Distal Renal Tubular Acidosis

SLC4A1

Pathogenic variants in *SLC4A1* affect the structure and/or function of the anion exchanger (AE1), a chloride/bicarbonate exchanger (Fig. 3) located in the basolateral membrane of the α-intercalated cells of the collecting duct and responsible for the transport of bicarbonate from the intracellular space to the systemic circulation. Retention of bicarbonate in the cytosol will cause an increase in the pH and therefore impairs the ability of the α-intercalated cell to secrete protons to the tubular lumen.

A different isoform of AE1, including an extended N-terminus, is expressed in the membrane of red blood cells where it was initially discovered and named "band 3 protein" [83, 91]. AE1 does not only control intracellular pH but also performs an important role in stabilizing the membrane structure of the erythrocytes.

AE1 dimers form a tetrameric macrocomplex between itself, the Rh complex, glycophorin A (GPA), and ankyrin, which links the membrane with the cell cytoskeleton [92]. Dysfunctional AE1 cannot adequately exchange anions and may induce a monovalent cation leak from the erythrocyte [93]. Carriers of specific heterozygous variants in *SLC4A1* have a mild hemolytic anemia due to destabilization of the erythrocyte membrane known as hereditary spherocytosis or Southeast Asian ovalocytosis (SAO) [94].

Most patients that carry pathogenic variants in *SLC4A1* have either a renal or a hematological phenotype, and there are different reasons:

1. Variants in the N-terminal fragment of the transmembrane protein not transcribed in the kidney will only affect red cell function.
2. Variants affecting intracellular sorting to the basolateral membrane will only affect kidney function, as the red cell is not polarized [95] and expresses chaperone proteins, such as Glycophorin A [96].
3. Variants causing distal renal tubular acidosis typically have a dominant negative effect, such as mistargeting or retention of the dimeric AE1 in the ER, whereas variants causing haploinsufficiency are associated with isolated red cell problems [96].

Some patients can develop distal renal tubular acidosis and chronic hemolysis [97]. This can occur in compound heterozygote individuals with an SAO and a distal renal tubular acidosis variant.

The erythrocyte cation leak from SAO variants has been linked to protection from Malaria infection, which would explain why such pathogenic variants are more prevalent in tropical areas [98].

SLC4A1-associated dRTA is typically inherited in an autosomal dominant fashion due to the dominant negative effect of the identified variants. However, *SLC4A1* variants associated with loss-of-function cause autosomal recessive dRTA.

ATP6V1B1 and *ATP6V0A4*

ATP6V1B1 and *ATP6V0A4* (formerly annotated as *ATP6N1B*) encode subunits of the vacuolar H^+-ATPase, located in the apical membrane of the α-intercalated cells (Fig. 3). This H^+-ATPase has two domains: a cytoplasmic or V1 domain, which hydrolyzes ATP and a transmembrane or V0 domain facilitating the actual transmembrane transport of protons, either to intracellular compartments or to the extracellular space [58]. Intracellularly, this vacuolar ATPase performs different tasks such as receptor-mediated endocytosis, membrane trafficking, prohormone synthesis, protein degradation, and neurotransmitter uptake, while it can also facilitate entry of various viruses and toxins. In the plasma membrane, they are involved in renal H^+ secretion, bone resorption, and sperm maturation [58].

V1 is the larger domain formed by eight different subunits (A-H) while V0 contains six subunits (a, d, e, c, c′ and c″) [99]. Isoforms B1 and a4 are expressed not only in the kidney but also in other tissues such as inner ear and epididymis, which explains why patients with pathogenic variants in these genes can have hearing loss. Despite acidification being a key factor for sperm cell conservation in the epididymis, male infertility has so far only been documented in the mouse model for *FOXI1* (see below) [100, 101].

ATP6V1B1 was the first recessive disease gene identified in dRTA, by investigating a cohort with concomitant bilateral, progressive, and early onset sensorineural hearing loss (SNHL) [84]. Specific radiological studies also revealed abnormally enlarged vestibular aqueducts; vertigo has been also described but appears to be rare [102, 103]. Subsequent investigations in individuals with dRTA without SNHL helped identify a second gene, *ATP6V1A4*, encoding a subunit of the V0 domain [85]. This cohort had a high prevalence of nephrocalcinosis and rickets with a very early age at presentation, and all had normal audiometry, suggesting a new subtype of dRTA without SNHL. Two years later, a subsequent study provided evidence for patients with mutations in *ATP6V0A4* also having hearing impairment albeit with a tendency to later onset, up to 33 years old [104].

FOXI1

FOXI1 encodes a forkhead transcription factor crucial in the expression of different proteins in acid-secreting epithelia, including: AE1, AE4, and the V-ATPase subunits B1, a4, A, and E2 [105]. Biallelic pathogenic variants in *FOXI1* are linked to a severe phenotype of dRTA with early and profound SNHL [86]. This phenotype had been previously reported in Foxi1 knockout mice, which also have male infertility [106]. Whether this particular phenotype will be relevant in humans is still unknown as follow-up data for the only male individual reported so far are limited to his childhood.

WDR72

WDR72 had been previously associated with amelogenesis imperfecta (AI) [90]. Later, recessive variants in *WDR72* were identified in two families affected by dRTA and AI [87], and subsequently further families were reported [107, 108]. The exact mechanisms by which *WDR72* variants cause distal renal tubular acidosis remain unclear at present. WDR72 has been implicated in intracellular vesicle trafficking [87]. Why some of these patients manifest either AI, dRTA, or both is also unclear. However, “reverse phenotyping” in one report showed that all individuals with dRTA and variants in *WDR72* also had AI [107]. Similarly, the late onset or absence of overt acidosis in some individuals with AI and *WDR72* variants may reflect that the dRTA phenotype can be mild or “incomplete” (see below) [108].

Other Genes

In most larger series, causative variants are identified in about 60–80% of patients with a clinical diagnosis of primary dRTA [16, 109], suggesting that further disease genes are yet to be identified.

Secondary dRTA

Secondary dRTA is typically associated with autoimmune disorders, especially Sjögren syndrome [110]. A list of reported causes is provided in Table 2.

Incomplete Distal Renal Tubular Acidosis

Incomplete dRTA refers to a disorder characterized by an impaired renal tubular acidification

Table 2 Conditions associated with secondary dRTA. Shown are conditions that are associated with dRTA and the presumed mechanisms. Urinary tract obstruction and hyponatriuretic states, as well as drugs blocking the epithelial sodium channel ENaC in the collecting duct (e.g., amiloride, trimethoprim) are typically associated with hyperkalemic or type 4 dRTA

Etiology	Examples	Presumed mechanism
Autoimmune disorders	Sjögren syndrome Systemic lupus erythematosus, Rheumatoid arthritis, autoimmune thyroid disease, primary biliary cirrhosis	Autoimmune response to antigens in the intercalated cells
Toxins/drugs	Amphotericin B Lithium Toluene Amiloride Trimethoprim Pentamidine Vanadium Calcineurin inhibitors	Damage to collecting duct cells or blockage of specific transport molecules associated with acid secretion
Nephrocalcinosis/ hypercalciuria	Primary hyperparathyroidism Hypercalcemic hyperthyroidism Vitamin D intoxication, idiopathic hypercalciuria, familial hypomagnesemia-hypercalciuria with nephrocalcinosis	Calcium-mediated damage/dysregulation of tubular cells
Hemoglobinopathy	Sickle cell disease	Ischemic damage to tubular epithelial cells
Renal transplantation	Rejection	Inflammatory damage to tubular epithelial cells
Urinary tract obstruction	Posterior urethral valves, obstructive bladder stone	Pressure-related distal tubular dysfunction
Hyponatriuretic states	Liver cirrhosis Nephrotic syndrome Congestive heart failure	Insufficient distal sodium delivery

without overt systemic acidosis that is generally identified during investigations for recurrent urinary stone disease. It was first reported in 1959 by Wrong and Davies while studying urine acidification in a large cohort of 68 individuals with oral ammonium chloride administration [9]. Although in the initial report the three identified patients with this condition did have nephrocalcinosis but no urolithiasis, subsequent studies have been highlighting also the high prevalence of recurrent stone disease in these individuals [111, 112].

Accurate estimations of the prevalence of incomplete dRTA in the general population are not possible to be established for several reasons including the lack of overt metabolic acidosis in normal situations plus the need of an acidification test for confirmation, a test with many associated difficulties, including nausea, vomiting, and abdominal pain, among others [113]. However, there is available data published in selected population such as stone formers, where the prevalence varies from as little as 2% to as high as 19% [112, 114, 115].

It is not very clear why some patients despite a tubular acidification defect do not present with overt systemic acidosis, but possible explanations include sufficient buffering produced by the skeleton via bone resorption. Indeed mineral bone disease and growth failure are both common features of children with incomplete dRTA and alkali supplementation has been shown to reverse this effect in children [116]. In adults, incomplete dRTA has been associated with low bone mineral density and risk of fractures. Studies in groups of patients with low mineral bone density have reported a substantial prevalence of incomplete dRTA up to 20% [117, 118].

The causes of incomplete dRTA may be the same as for the complete form, and some clinicians consider incomplete and complete dRTA as part of a continuum, where the former is preceding the latter. Different case reports in children support this hypothesis, particularly in patients with dominant dRTA, where incomplete dRTA during early childhood may be followed by systemic acidosis in later years [4, 119]. In addition, incomplete dRTA has been associated with heterozygous variants in *ATP6V1B1* and ATP6V04 (and the corresponding heterozygous knock-out mice), perhaps denoting some degree of haploinsufficiency or a mild dominant negative effect [120, 121]. Incomplete dRTA has also been described in patients with medullary sponge kidney [122], Sjögren syndrome [123], nephrocalcinosis [124], and drug toxicity.

Patients with incomplete dRTA have a higher risk of stone formation/nephrocalcinosis and share a similar urinary metabolic profile (hypocitraturia and more alkaline urine) with complete dRTA. Stone composition is therefore also similar (>95% of carbonate apatite in occasions) [125], although hypercalciuria is only variably associated with incomplete dRTA [126].

As with the full form, the treatment of patients with incomplete dRTA and recurrent stone formation is alkali supplementation. Because of the low prevalence of the disease in the general population, large randomized control trials assessing treatment are lacking. Nevertheless, citrate supplementation has been shown to improve bone health in longitudinal studies, while alkali therapy in the pediatric population had a positive impact on height SDS in both complete and incomplete dRTA [116, 127].

Diagnosis

History and Examination

Patients with dRTA typically present with nonspecific symptoms, mainly failure to thrive. Occasionally, hypokalemia-related complications may predominate. Some may also have associated rickets. Subjects with dominant dRTA may present later in childhood or adolescence with urolithiasis [65]. Key to the diagnosis are blood and urine tests.

Biochemistry: Blood

The suspicion of a diagnosis of dRTA usually follows the finding of a normal anion gap/hyperchloremic metabolic acidosis and hypokalemia. This constellation of findings is typical for bicarbonate loss, and in the absence of a history or signs of enteric losses, a diagnosis of RTA must be considered.

Biochemistry: Urine

The next diagnostic step is then assessment of the urine to distinguish between proximal and distal RTA.

Urine pH

The first important urine data is the pH. In pRTA, distal acidification is intact, and once the blood bicarbonate level is below the threshold for reabsorption, bicarbonaturia resolves and urine pH can reach maximal acidity. Thus, in pRTA prior to bicarbonate supplementation, urine pH is typically <5.3. In contrast, in dRTA, urinary acidification is impaired and urine pH is >5.3.

There are a few potential problems with measurement of urine pH:

- If urine is exposed to air, CO_2 will diffuse from urine into air, thereby lowering the concentration of both HCO_3^- and H^+ in the urine, leading to an artificially elevated urine Ph.
- Urea-splitting organisms will increase the concentration of NH_3 in the urine, leading to an artificially elevated urine Ph.

Thus, urinary pH should be measured in freshly voided samples, or ones obtained under oil to prevent CO_2 diffusion, which can be challenging in non-toilet-trained patients, such as infants. And while a pH meter is the most accurate means of determining urine pH, pH strips or multistix dipped in the urine may be more practical, if they avoid potential delays from sending the urine to the lab. If pH strips are used, an upper pH limit for maximal acidification of 5.5 is commonly used.

Urinary Anion Gap

Protons in the urine are mostly buffered by NH_3 (ammonia) to form NH_4^+(ammonium). Consequently, in an acidotic patient with normal urinary acidification, the urine contains a substantial concentration of NH_4^+. The absence of urinary NH_4^+ thus indicates a defect in distal acidification. In clinical practice, few laboratories routinely perform urinary NH_4^+ measurement, but it can be indirectly assessed, via the urine anion gap (UAG).

The main ionic components of urine are Na^+, K^+, and Cl^-. In analogy to plasma, a UAG can be calculated: $UAG = Na^+ + K^+ - Cl^-$. However, in contrast to the plasma anion gap, the UAG is expected to be negative during acidosis, reflecting an excess of unmeasured cations in the urine (NH_4^+). For this reason, it can also be referred to as the "urine cation gap." In patients with dRTA, the concentration of NH_4^+ in the urine is low, because of the impaired ability of the kidney to excrete protons. Thus, in distal RTA, the cation gap is absent and the UAG is positive (reviewed in [128]). Calculation of the UAG can therefore be used as an indirect assessment of distal urinary acidification, with a positive UAG indicating dRTA. Obviously, the calculation of the UAG is only meaningful in patients with acidosis, as patients with an alkali load will physiologically have a positive UAG. It also should not be used in patients with advanced kidney disease [129]. Moreover, if the urine contains substantial concentrations of other unmeasured cations, such as ketoacids, salicylates, or penicillin, the UAG should be used cautiously [130].

Urinary pCO_2

The use of pCO_2 in the assessment of urinary acidification was first proposed in 1974 [131]. It is based on the rationale that urinary pCO_2 should increase during urinary acidification, because of proton secretion and carbanhydrase activity, generating H_2O and CO_2 [132, 133]. The same technical problem of CO_2 diffusion (discussed under "urine pH" above) applies to urine pCO_2 measurement, and in clinical practice, this test is rarely, if ever, used.

Stimulation Tests of Urinary Acidification

Patients suspected of having incomplete dRTA, i.e., without overt acidosis, will need special tests to assess their maximal urinary acidification. Acidification tests with either hydrochloric acid (HCl) or ammonium chloride (NH_4Cl) had been used for many decades but were complicated and required sometimes up to 5 days of study. The short NH_4Cl test proposed by Wrong and Davies constitutes an easier and more practical test that subsequently became the gold standard in diagnosis [7, 9]. However, many patients have difficulties tolerating NH_4Cl, and for this reason, alternative tests have been proposed.

The Short Ammonium Chloride Test

The initial protocol was based on a single and slow (about 1 h) oral administration of 100 mg/kg ammonium chloride. Tolerance to the test tends to be challenging due to early development of nausea and vomiting. Alternative doses of 75 mg/m^2 in infants diluted and administrated via nasogastric tube have been described [134]. The entire test takes about 6–8 h to be completed and includes a baseline serum sample, and a control 2–4 h post NH_4Cl is given to confirm that metabolic acidosis has been induced ($tCO_2 < 21.0$ or 18.0 mmol/L in infants) plus serial urines. Individuals with normal urinary acidification capacity can drop urine pH under 5.3 and generally between 4.6 and 5.0. Urinary ammonium, if measured, is expected to rise.

The Prolonged Ammonium Chloride Test

To facilitate better tolerance, a prolonged test using a lower dose (50 mg/kg/day), but repeated over 3 days, has been proposed [135].

Furosemide Testing

The furosemide test is based on the observation that the administration of loop diuretics like furosemide increases distal sodium delivery, as well as aldosterone secretion with consequent generation of a negative transmembrane voltage which will favor H^+ secretion into the tubular lumen [136–138].

The suggested furosemide dose is 1 mg/kg and administration either intravenous or orally with urine samples being collected during a period of 4 h. Urinary pH in normal individuals should drop below 5.3 whereas urine NH_4^+ and potassium excretion increase 2–3 times with respect to baseline values [138, 139].

Furosemide + Fludrocortisone Testing

The furosemide test was later modified to maximize stimulation by addition of exogenous mineralcorticoids [137]. A standard adult protocol uses furosemide (40 mg) and fludrocortisone (1 mg). Performance is better tolerated by the patients with no gastric irritation, and acidification capacity is equivalent to ammonium chloride test but significantly quicker [140]. In patients with recurrent urolithiasis, the F + F test has been reported to have a sensitivity of 85% and a specificity of 77%, compared to the short ammonium chloride test. However, the positive predictive value was only about 30%, whereas the negative predictive value was 98%, using the ammonium chloride loading test as a gold standard [141]. Thus, in adult stone-forming patients, a positive F+F test may need to be confirmed by a formal ammonium chloride-loading test.

Other Urine Abnormalities

Patients with dRTA occasionally have additional transient features of proximal tubular dysfunction, typically low-molecular weight proteinuria, aminoaciduria, and less commonly, phosphaturia [4, 43, 59–61]. In one series, this selective proximal tubular dysfunction was noted in 67% of dRTA patients at presentation [4]. The etiology of this proximal tubulopathy in dRTA is unclear but is commonly ascribed to the hypokalemic acidosis, as it resolves with treatment [60]. Interestingly, glycosuria has so far not been reported in this transient proximal tubular dysfunction in dRTA, and the presence of glucose in the urine would thus make a diagnosis of dRTA less likely [4].

Imaging

Medullary nephrocalcinosis is present in almost all patients [138]. Urolithiasis, although more prevalent in adulthood, can also present earlier [142].

Genetic Testing

Genetic testing should be offered to all patients with suspected inherited dRTA to confirm the diagnosis and facilitate genetic counseling. Early presentation, particularly in the first decade of life is very suggestive of an inherited form of distal renal tubular acidosis, although up to 10% of the patients can be diagnosed in adult life. Some clinical details can already provide clues as to the underlying gene: a positive family history with dominant inheritance suggests *SLC4A1*, whereas the presence of sensorineural hearing loss suggests one of the H^+ pump subunits or the transcription factor *FOXI1* as an underlying cause. Finally, the presence of enamel disorder suggests *WDR72*.

Treatment

The most important aspect of dRTA is that it is a treatable disease. Alkali supplementation, sufficient to match the daily acid load generated by the diet and bone metabolism, will normalize the biochemical abnormalities and most of the associated complications.

There are numerous different alkali supplementations available differing by:

1. Type of alkali (bicarbonate and/or citrate).
2. Type of salt (sodium, potassium, but also other alternatives as calcium or magnesium are available).
3. Formulation (liquid, tablets, immediate versus prolonged released).

In general, citrate forms are more frequently prescribed, presumably as at least in liquid formulations, and the alkali is usually more concentrated (2–3 mEq/ml) than in those containing bicarbonate (1 mEq/ml), thereby reducing the volume of medication needed. However, there is no solid evidence that citrate supplementation leads to a less lithogenic urine profile than bicarbonate [143, 144]. A large international study with 340 individuals diagnosed with primary distal renal tubular acidosis also showed no differences in metabolic control or long-term outcomes between patients taking sodium bicarbonate and sodium/potassium citrate [142]. And each form may cause problems with tolerability: Many patients find that citrate causes dyspepsia, whereas sodium bicarbonate may cause bloating and belching.

Recent trials of a new prolonged release formulation of potassium-bicarbonate and -citrate have shown a better gastrointestinal tolerance compared to standard treatment as well as improved metabolic control with only two administrations per day [145, 146]. However, real-world experience with this drug has yet to be reported.

In clinical practice, pragmatic considerations, such as local availability, affordability, and palatability, are probably most important to support effective treatment and compliance. If a Na^+-containing formulation is used, separate K^+ supplementation may be necessary to maintain normal plasma levels.

Dosage and frequency of alkali supplementation depend on multiple factors most notably the age of the patient: Infants have been prescribed doses up to 8–10 mEq/kg/day while older children and adults typically receive doses around 2–3 mEq/kg/day [4, 136]. Other factors include the underlying molecular basis, as well as diet (see below).

Infrequent administration of large doses of alkali supplementation may briefly increase blood bicarbonate levels above the threshold for proximal reabsorption, leading to loss of bicarbonate in the urine and potentially subsequent acidosis, once the remaining bicarbonate has been used up for buffering. To prevent this, administration should be several times a day. In infants, the total dose may be split up in small aliquots given with each feed, helping not only to maintain metabolic control but also minimizing side effects from unpleasant taste. In older children, less frequent dosing (3–4 times daily) is likely to help compliance and allow uninterrupted sleep. With the new extended release formulation, two daily administrations have been found to be safe and effective with potentially better compliance [146].

Mixed Proximal and Distal Renal Tubular Acidosis (Type III)

A combined pattern of proximal and distal features of RTA is observed in patients with impaired function in the enzyme carbonic anhydrase type II. This cytosolic enzyme is involved in the generation of carbonic acid from CO_2 and water in both proximal and distal segments of the nephron, facilitating bicarbonate reabsorption through the basolateral membrane to the interstitium and subsequently systemic circulation. Besides the kidney, CAII is also expressed in the brain and skeleton, and patients with CA II deficiency generally present with osteopetrosis, cerebral calcifications, as well as proximal and distal RTA. Early onset of hypokalemia, paroxysmal muscle weakness, moderate-to-severe neurodevelopment delay, and growth retardation are other associated features [12]. Characteristic biochemical findings besides the hypokalemic, hyperchloremic metabolic acidosis typical for all RTA reflect the combined proximal and distal defect: urinary bicarbonate wasting, failure to acidify urine below a pH of 5.5, a low urine-to-blood pCO2 difference in an alkaline urine, and decreased ammonium excretion [147].

CA type II is encoded by the *CA2* gene (OMIM #611492), and the associated disorder is inherited in an autosomal recessive inheritance pattern. Although more than 20 different pathogenic variants have been identified so far in individuals from different ethnic backgrounds, >70% of cases have been reported in the Maghreb [51, 148]. The splice variant (c.232 + 1G > A) identified repeatedly in Arabic patients is associated with a more severe phenotype compared to other cases in America and Europe associated with a missense variant (H107Y) [149].

Treatment of the acidosis is with alkali supplementation. The osteopetrosis can be treated with bone marrow transplantation.

Hyperkalemic Renal Tubular Acidosis (Type IV)

Type IV RTA is characterized by impaired aldosterone action: either due to deficiency or to resistance [39]. It is thus primarily a disorder of tubular salt handling and, because of the hyperkalemia, can be easily distinguished from any of the other presentations of RTA.

Pathophysiology

Aldosterone is involved in distal tubular acidification in several ways:

1. Stimulation of sodium reabsorption in the principal cells of the collecting duct. The resultant lumen negative electrical potential facilitates proton secretion and potassium secretion.
2. Upregulation of the expression of the H^+-ATPase and of the carbonic anhydrase in alpha-intercalated cells [150].
3. Stimulation of ammonia synthesis in the proximal tubule [151].

Aldosterone Deficiency

Aldosterone deficiency can be secondary to a generalized adrenal gland impairment, commonly known as Addison disease or to a specific inherited mineralcorticoid deficiency such as congenital adrenal hyperplasia (CAH). Isolated aldosterone synthase deficiency is a very rare condition but less severe than CAH as the glucocorticoid activity is generally preserved [152].

Aldosterone Resistance

Pseudohypoaldosteronism (PHA) refers to a condition where aldosterone secretion is unimpaired, but the kidney is unable to respond to it normally.

Pseudohypoaldosteronism Type 1 (PHA1)

Typically presents in early infancy. It is characterized by salt-wasting, hyperkalemia, and metabolic acidosis in the presence of markedly elevated plasma renin activity and aldosterone concentration. PHA1 does have two different inheritance patterns:

- An autosomal dominant form, due to heterozygous variants in the *NR3C2* gene, encoding the mineralocorticoid receptor. Clinical manifestations are limited to the kidney [153].
- An autosomal recessive form caused by biallelic loss-of-function variants in the genes encoding one of the three constitutive subunits (α- *SCNN1A*, β- *SCNN1B*, and γ- *SCNN1G*) of the epithelial Na^+ channel. Due to the expression pattern of this channel, clinical manifestations extend to different organs (kidney, large bowel, lung, and sweat and salivary glands) [154].

Pseudohypoaldosteronism Type 2 (PHA2 or Gordon Syndrome)

PHA2 is also characterized by hyperkalemia and metabolic acidosis, but in contrast to PHA1 by salt retention with consequent hypertension and suppressed plasma renin activity.

Four underlying genes have been identified: *WNK1*, WNK4, *KLHL3*, and *CUL3* [39]. Inheritance is typically autosomal dominant, except for *KLHL3* which can be associated with both dominant and recessive variants. Variants in *CUL3* are typically de novo and tend to be associated with extrarenal manifestation, especially growth failure [155].

Acquired Type IV RTA

Acquired aldosterone deficiency is rare in childhood and is typically associated with obstructive uropathy and interstitial kidney disease, such as pyelonephritis or tubulointerstitial nephritis. Medications causing type IV RTA obviously include those designed to interfere with aldosterone production or action, such as angiotensin-converting enzyme inhibitors, angiotensin receptor blockers, and potassium-sparing diuretics, such as the mineralocorticoid receptor blockers spironolactone and eplerenone or the ENaC blocker amiloride.

An acquired form of PHA2 can be seen in transplanted patients treated with calcineurin inhibitors [156].

Treatment

Treatment and prognosis depend on the underlying cause. In acquired forms, the underlying cause should be eliminated. Fludrocortisone is used in aldosterone deficiency. PHA1 is treated with sodium chloride and sodium bicarbonate supplementation and often with sodium-potassium exchange resins. PHA2 responds well to treatment with thiazides [59, 60].

Abstract

Hereditary tubular transport disorders that lead to abnormal aminoaciduria and glycosuria are uncommon but are of major biologic importance. Some of these diseases can be associated with significant morbidity. In the past two decades, remarkable progress has been made in our understanding of the molecular pathogenesis of hereditary aminoaciduria and glycosuria. Molecular genetics and molecular biology studies have led to the identification of numerous mutations resulting in aminoaciduria and glycosuria, have provided important insight into the defective molecular mechanisms underlying these disorders, and have greatly increased our understanding of the physiology of renal tubular reclamation of amino acids and glucose.

This chapter summarizes the general characteristics of proximal tubular transport of amino acids and glucose, discusses the

specificity and classification of amino acid and glucose transport systems, reviews the molecular pathophysiology and genetic aspects of hereditary aminoaciduria and glycosuria, describes the clinical features of these tubulopathies, and summarizes their therapy. Special emphasis is given to cystinuria, lysinuric protein intolerance, Hartnup disease, iminoglycinuria, dicarboxylic aminoaciduria, familial renal glycosuria, and Fanconi-Bickel syndrome.

Further molecular studies of inherited proximal tubular transport disorders resulting in aminoaciduria and glycosuria may shed more light on the molecular pathophysiology of these diseases and may significantly improve our understanding of the mechanisms underlying renal handling of amino acids and glucose in health and disease. The identification of the molecular defects in these inherited tubulopathies may provide a basis for future design of targeted therapeutic interventions for molecular therapy of these complex disorders.

Introduction

Only negligible amounts of amino acids and glucose are normally present in the final urine, reflecting very efficient reabsorption mechanisms for these organic solutes in the proximal tubule. Renal tubular transport defects or specific metabolic abnormalities result in excretion of significant quantities of amino acids or glucose in the urine. Although hereditary defects in renal tubular transport of most of these substances are uncommon, they are of major biologic importance. First, some of these membrane transport disorders (e.g., cystinuria, lysinuric protein intolerance, Hartnup disease, Fancoi-Bickel syndrome) are associated with significant morbidity. Second, the study of these disorders has provided much insight into the physiology of renal tubular reclamation of amino acids and glucose and into the specific metabolic pathways that control their reabsorption and has been crucial in understanding the genetics of tubular transport systems.

This chapter summarizes the general characteristics of renal tubular transport of amino acids and glucose, outlines the two main classifications used for amino acid transport systems (based on chemical properties/substrate specificity and sequence homology/structural features), and discusses the specific hereditary membrane transport disorders that result in abnormal aminoaciduria and glycosuria. Special emphasis is given to cystinuria, lysinuric protein intolerance, Hartnup disease, iminoglycinuria, dicarboxylic aminoaciduria, familial renal glycosuria, and Fanconi-Bickel syndrome, including molecular and genetic aspects of these diseases. This chapter does not discuss overflow aminoaciduria and glycosuria, which occur when the filtered load of these solutes exceeds the transport capacity of the renal tubule. The conditions leading to tubular overload include various inborn errors of amino acid metabolism and diabetes mellitus, which result in elevated plasma levels of amino acids and glucose, respectively. Fanconi syndrome, a proximal tubular disorder characterized by generalized aminoaciduria, and urinary hyperexcretion of glucose, bicarbonate, phosphate, and other solutes, is discussed in ► Chap. 37, “Cystinosis.”

Aminoaciduria

General Characteristics of Tubular Amino Acid Transport

Circulating free amino acids are derived from dietary proteins that are hydrolyzed and absorbed in the intestine, from intracellular catabolism of peptides, and from de novo synthesis within cells. More than 99% of the load of free amino acid filtered by the kidneys of humans and other mammals is reabsorbed in the renal tubule and returned to plasma [1–3]. Amino acid reabsorption occurs predominantly in the pars convoluta of the proximal tubule and, to a small extent, in the pars recta [1, 3]. Amino acids are reabsorbed primarily from tubular lumen by an active transport across the luminal membrane [1]. In studies using renal brush-border membrane vesicles (BBMV) from various animals to explore amino acid transport across this membrane, the rate of accumulation by vesicles and the magnitude of the overshoot, which indicates active concentrative transport, was greatly augmented by an external Na^+ gradient across the vesicle membrane [1]. Hence, it is widely accepted that uptake of most amino acids at the brush-border surface occurs by Na^+-amino acid cotransport driven by the electrochemical Na^+ gradient from the tubular lumen to the cell [1, 3] (Fig. 1). Maintenance of the Na^+ gradient is established by the Na^+-K^+-ATPase, which is located at the basolateral membrane and which transports Na^+ out of and K^+ into the cell. An additional driving force for amino acid transport across the luminal membrane is the H^+ gradient (luminal > intracellular) which drives uptake of proline [4] and glycine [5] by BBMV. Finally, cationic acids and cystine are reabsorbed across the luminal membrane in exchange for recycled neutral amino acids [2, 6] (Fig. 1).

Active amino acid transport across the brush-border membrane is followed by efflux, mainly via carrier-mediated, Na^+-independent, facilitated diffusion or exchange from the cell into the peritubular space across the basolateral membrane [2, 7] (Fig. 1). Thus, under normal conditions, net transepithelial movement of amino acids occurs from the tubular lumen to the peritubular space. However, net transepithelial flux of amino acids occurs from the combination amino acid transport in both directions, namely, lumen → interstitium and interstitium → lumen [2, 7, 8]. Indeed, the basolateral membrane harbors active Na^+-dependent and Na^+-independent transport and exchange systems mediating amino acid uptake in the tubular cell (Fig. 1), and diffusional backflux of amino acids from cell into the tubular lumen is a well-documented phenomenon [2, 7]. Interstitium → lumen oriented backflux through paracellular pathways also occurs. The sum of these vectoral fluxes determines the direction and the rate of transepithelial amino acid transport. These competing forces are important in understanding renal tubular amino acid transport, particularly in disease states and during maturation [8, 9, 10].

Na^+-amino acid symport across the luminal membrane is a carrier-mediated saturable process obeying Michaelis-Menten kinetics [1, 3]. The effectiveness of the active reabsorption process for a specific amino acid depends on the ratio $V_{max}:K_m$ [1]. A low V_{max} (decreased transport capacity) or a high K_m (diminished transporter-substrate affinity) for a given amino acid results in decreased reabsorption rate of this amino acid. Changes in efficiency or capacity of amino acid transport also have an important role in both neonatal aminoaciduria and hereditary aminoacidurias.

Microperfusion and micropuncture experiments and studies using BBMV for various amino acids [1] have identified two or more Na^+-linked transport systems with different kinetic characteristics. Having multiple transport systems for the same amino acid becomes very meaningful if reduced concentrations of filtered amino acid are presented to the proximal straight tubule. For example, in the case of glycine, two Na^+-dependent, active transport systems have been characterized along the luminal membrane of the isolated perfused proximal tubule [11]: a low-affinity, high-capacity system in the convoluted segment and a high-affinity, low-capacity system in the straight segment. The latter system absorbs less glycine against a greater concentration gradient and likely leads to lower luminal glycine concentrations than could be achieved in the proximal convoluted tubule [7, 11]. This axial

Fig. 1 Summary of amino acid transport mechanisms in the proximal tubule. Filled circles indicate Na^+-dependent, active, carrier-mediated cotransport or antiport (exchange). Dashed circles indicate H^+-dependent, active, carrier-mediated cotransport. Empty circles indicate Na^+-independent antiport or uniport (facilitated diffusion). Half-filled, half-dashed, or half-empty circles indicate various combinations of the above. Known or suspected transport defects leading to different hereditary aminoacidurias are depicted; AA^0, neutral amino acids; AA^+, basic amino acids; AA^-, acidic amino acids; CssC, cystine; Cys, cysteine. See text for details

heterogeneity of Na^+-linked amino acid uptake systems with respect to kinetic characteristics has been demonstrated for several amino acids in BBMV derived from pars convoluta and pars recta of the proximal tubule [1]. The recognition of several transport systems for the same amino acid as well as their axial heterogeneity is of major importance in understanding the pathophysiology of hereditary aminoaciduria.

One or more Na^+ ions are transported for each amino acid molecule translocated, and with most amino acids, this process is electrogenic-positive driven by a negative cell interior [1, 12]. Na^+-amino acid stoichiometry determines the electrogenicity and efficiency of the transport system [7]. Additional ions besides Na^+ are involved in the translocation of the amino acid carrier complex across the brush-border membrane [1]. Taurine [13], glycine [14], and proline [15] transport, for example, operates by means of 2 or 3 Na^+/1 Cl^-/1 amino acid carrier complex.

Specificity and Classification of Amino Acid Transport Systems

It has been well established that several distinct chemical group-specific Na^+-dependent transport systems for amino acids exist in the tubular luminal membrane [1–3]. Evidence for these systems has been derived from a variety of microperfusion experiments and vesicle studies and, in humans, from the existence of inborn errors of renal tubular transport that can be explained only by defects in specific transport pathways [1, 2, 16]. These include systems for dibasic (cationic) amino acids, cystine, acidic (anionic) amino acids, neutral α-amino acids, imino acids, glycine, and β- and γ-amino acids. In addition to separate systems for L-cystine and the dibasic amino acids (L-lysine, L-arginine, and L-ornithine), these amino acids likely share a common transport pathway [1, 2], as suggested by the urinary hyperexcretion of all four amino acids in cystinuria (see Cystinuria below).

The broad-specificity transport pathway for neutral α-amino acids, which is a low-affinity, high-capacity system, is located in the proximal convoluted tubule [16]. However, there are several alternative specific renal transport systems for neutral amino acids, including high-affinity systems located in the proximal straight tubule. The presence of such pathways is also suggested by the finding of isolated transport defects for neutral amino acids (see Neutral Aminoaciduria). The imino acids proline and hydroxyproline are reabsorbed by at least three systems: a low-affinity/high-capacity system in the proximal convoluted tubule shared with glycine; an imino acid-specific, high-affinity/low-capacity system in the proximal straight tubule; and a separate high-affinity/low-capacity system for glycine in the late proximal tubule [11].

Classification of Amino Acid Transport Systems by Chemical Properties/Substrate Specificity

The investigation of amino acid transport pathways in the plasma membrane of mammalian cells has delineated several transport systems which are classified according to their chemical properties/substrate specificity [2, 6, 17, 18, 19] (Table 1; Fig. 1). Most of these transport systems also have been identified in the kidney [2, 6, 17, 18, 20]. The neutral amino acid transport systems include the Na^+-dependent, concentrative B^0 system (for most neutral amino acids), A and ASC systems (for small neutral amino acids), and N system (for glutamine, asparagine, and histidine); the Na^+- and Cl^- -dependent Imino system (for proline and hydroxyproline), Gly system (for glycine and alanine), and BETA system (for taurine, β-alanine, and γ-aminobutyric acid); the H^+ gradient-dependent PAT system (for imino acids and glycine); as well as the Na^+-independent, nonconcentrative L system (for bulky neutral, branched-chain amino acids and cysteine) and the T system (for aromatic amino acids). The cationic amino acid transport systems include the $b^{0,+}$ system (for dibasic and neutral amino acids including cystine), y^+ system (for the dibasic amino acids lysine, arginine, and ornithine), and y^+L system (for dibasic and neutral amino acids excluding cystine). The anionic amino acid transport system includes the Na^+- and H^+- dependent X^-_{AG} system (for acidic amino acids). Systems B^0,

EPT early proximal tubule (S1, S2 segments), *BBM* brush-border membrane
LPT late proximal tubule (S3 segment), *BLM* basolateral membrane

X^-_{AG}, Imino, Gly, β, PAT, and $b^{0,+}$ operate in the luminal membrane, whereas systems A, ASC, N, L, T, y^+, and y^+L operate in the basolateral membrane [2, 18, 20] (Fig. 1). The basolateral membrane-bound systems ASC, L, y^+, and y^+L as well as the luminal membrane-bound $b^{0,+}$ system function as antiport (exchange) systems [3, 18, 19] (Fig. 1).

Classification of Amino Acid Transport Systems by Sequence Homology/ Structural Features

Over the past two decades, molecular biology techniques had led to elucidating the molecular structure of various membrane-bound transport proteins, including amino acid transporters. The identification of brush-border membrane transporters was pioneered by Hediger et al. [45], who cloned the small intestinal Na^+-glucose cotransporter (see Molecular Biology of Na^+-Glucose Cotransporters) using expression cloning in *Xenopus* oocytes. Similar approaches have been used to clone, functionally express, and sequence various amino acid transporters. This has led to the classification of amino acid transporters based on gene homology using the solute carrier family (SLC) nomenclature introduced by the Human Genome Organization (HUGO) [22].

The sequence homology and structural features of amino acid transporters have led to their categorization into seven different gene families [2, 3, 18, 23, 24, 25] (Table 1): **(i)** the SLC1 or EAAT/ ASCT family (Na^+-dependent anionic/neutral amino acid transporters), **(ii)** the SLC6 family [Na^+- (and $C1^-$ -)dependent transporters], **(iii)** the SLC3/SLC7 or HAT family (cationic/neutral amino acid transporters), **(iv)** the SLC7 or CAT/LSHAT family (cationic/neutral amino acid transporters), **(v)** the SLC16 or TAT family (aromatic amino acid transporters), **(vi)** the SLC36 or PAT family (proton-coupled imino acid transporters), and **(vii)** the SLC38 or SNAT family (Na^+-coupled neutral amino acid transporters). As opposed to all other SLC families that contain multiple transmembrane domains [25], members of the SLC3 family function as components or subunits of heteromeric carriers (see Cystinuria).

Hereditary Aminoacidurias

Aminoacidurias are a group of disorders in which a single amino acid or a group of amino acids are excreted in excess amounts in the urine due to decreased tubular reabsorption. The defective tubular reabsorption is assumed to result from a genetic defect in a specific transport system that directs the reabsorption of these amino acids under normal conditions. Some of these disorders also involve a similar transport abnormality in the intestine. As opposed to inborn errors of amino acid metabolism, in which plasma levels of amino acids are elevated, resulting in overflow aminoaciduria, plasma levels of amino acids in hereditary aminoacidurias are largely normal. The aminoacidurias are generally categorized into five major groups according to the group-specific transport pathway presumed to be affected (Table 2). The groups are further subdivided into several disorders, based on the profile of the affected amino acids within that group (Table 2; Fig. 1).

Cationic Aminoaciduria

Four distinct cationic amino acid transport defects have been identified: *(a)* cystinuria, *(b)* hyperdibasic aminoaciduria, *(c)* lysinuric protein intolerance, and *(d)* isolated lysinuria. These diseases differ in identified or putative transport systems affected, pathophysiology, organs involved, and clinical features. Cystinuria is the prototype for this group of hereditary aminoacidurias.

Cystinuria Cystinuria (OMIM 220100) is an autosomal-recessive disorder of amino acid transport characterized by excessive urinary excretion of cystine and the dibasic amino acids lysine, arginine, and ornithine that have structural similarity (two amino groups separated by four to six chemical bonds). The pathogenic mechanism of cystinuria is defective transepithelial transport of these amino acids in the proximal tubule and the small intestine [26]. The very low solubility of cystine in the urine results in cystine stone formation in homozygous patients. Lysine, arginine, and ornithine do not form urinary stones as they are much more soluble than cystine. Urinary cystine calculi may produce considerable morbidity including urinary obstruction, colic, infection, and, in severe cases, loss of kidney function. Cystinuria accounts for 1–2% of all cases of urolithiasis and 4–5% of urolithiasis cases in children [27, 28]. The defective gastrointestinal transport

of cystine and dibasic amino acids in cystinuria does not result in intestinal disease.

Transport Defect Normally only 1% of the filtered cystine and dibasic amino acids is excreted. In cystinuria, cystine clearance may be near or equal to the glomerular filtration rate (GFR). Lysine and ornithine clearance is 30–80% of the GFR, whereas arginine excretion is lower [28]. Studies using isolated cortical tubules and BBMV [1, 29] have provided evidence for three brush-border membrane-bound and two basolateral membrane-bound carrier systems for cationic amino acids in the kidney. Transport at the brush-border membrane occurs by a system shared by cystine and the dibasic amino acids, a system specific for cystine, and a system specific for dibasic amino acids. It is the shared high-affinity, low-K_m system located in the S3 segment of the proximal tubule and identified as system $b^{0,+}$ (see Specificity and Classification of Amino Acid Transport Systems; Figs. 1 and 2) that is defective in cystinuria. The low-affinity, high-K_m, cystine-specific system and the low-affinity, dibasic amino acid-specific system, both located in the S1–S2 segments of the proximal tubule, have remained unidentified at the cellular/molecular level. The antiluminal membrane harbors two specific systems, one for dibasic amino acids identified as system y^+L (see Specificity and Classification of Amino Acid Transport Systems; Figs. 1 and 2) and one for cystine, but no shared system. These luminal and basolateral transport mechanisms mediate uptake and efflux of these amino acids across the basolateral membrane, respectively. The brush-border membrane of the intestinal cell has a single high-affinity, low-K_m, shared $b^{0,+}$ transport system for cystine and dibasic amino acids that is defective in cystinuria. Like kidney cells, intestinal cells have two basolateral membrane-bound, unshared/specific transport systems, one (system y^+L) for dibasic amino acids and one for cystine [2, 3]. The basolateral membrane-bound y^+L transporter for dibasic amino acids in the kidney and the intestine is defective in lysinuric protein intolerance (see Lysinuric Protein Intolerance). Amino acid transport in parenchymal cells and leukocytes from cystinuric patients is not impaired [2, 3] because

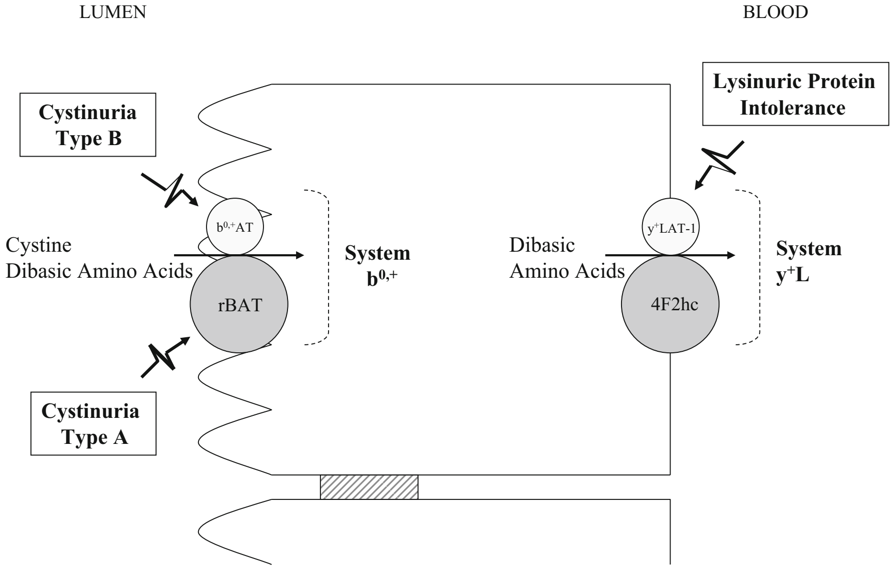

Fig. 2 Transport pathways for cystine and dibasic amino acids at the luminal and basolateral membranes of a proximal tubular cell. *Large circles* represent the heavy subunits and *small circles* the light subunits of the heteromeric amino acid transporters $b^{0,+}$ and y^+L. Hereditary aminoacidurias caused by defects in these transporters are depicted. (Modified with permission from ref. #45)

the transport defects are not found in the plasma membrane of these cells.

Prevalence Cystinuria is inherited in an autosomal-recessive fashion. Among the various types of aminoacidurias, it is a common disorder with an overall prevalence of 1:7000 to 1:15,000 and estimated gene frequency of 0.01 [26]. A very high prevalence of 1:2500 is observed in Israeli Jews of Libyan origin [30].

Classification Three phenotypes of cystinuria (types I, II, and III) have traditionally been described on the basis of the urinary excretion of cystine in the obligate heterozygous parents [31, 32]. More recently, a genotypic classification of cystinuria was introduced [33]. Most patients have genotype AA or BB, which denotes two mutated alleles in the genes *SLC3A1* or *SLC7A9*, respectively (see Molecular Genetics). A0 and B0 denote the identification of only one mutated allele, i.e., heterozygous carriers. Carriers with the A0 genotype usually have normal cystine excretion, while carriers with the B0 genotype have often elevated cystine excretion; they very rarely develop stones [34].

Molecular Genetics The heteromeric amino acid transporters (HAT), implicated in cystinuria (and in lysinuric protein intolerance; see later), are composed of a heavy subunit (SLC3; HSHAT) and a light subunit (SLC7; LSHAT) which are linked by a conserved disulfide bridge [23, 35, 36, 37, 38] (Fig. 3). The heavy subunit appears essential for trafficking the transporter to the membrane, whereas the light subunit confers the transporter function [25, 37].

Using linkage analysis in 17 cystinuric families, Pras et al. demonstrated linkage between cystinuria and three genetic markers on chromosome 2p, providing strong evidence that rBAT/SLC3A1 was the gene causing the disease [39]. Calonge et al. identified six specific mutations in the *SLC3A1* gene that segregated with a cystinuria phenotype, thereby establishing the rBAT gene, which encodes the heavy subunit of $b^{0,+}$, as a cystinuria gene (Fig. 2) [40]. To date, a total of 163 different rBAT mutations have been reported in patients with type A cystinuria [26, 41]. These mutations include nonsense, missense, splice site, and frameshift mutations, as well as large deletions and chromosome

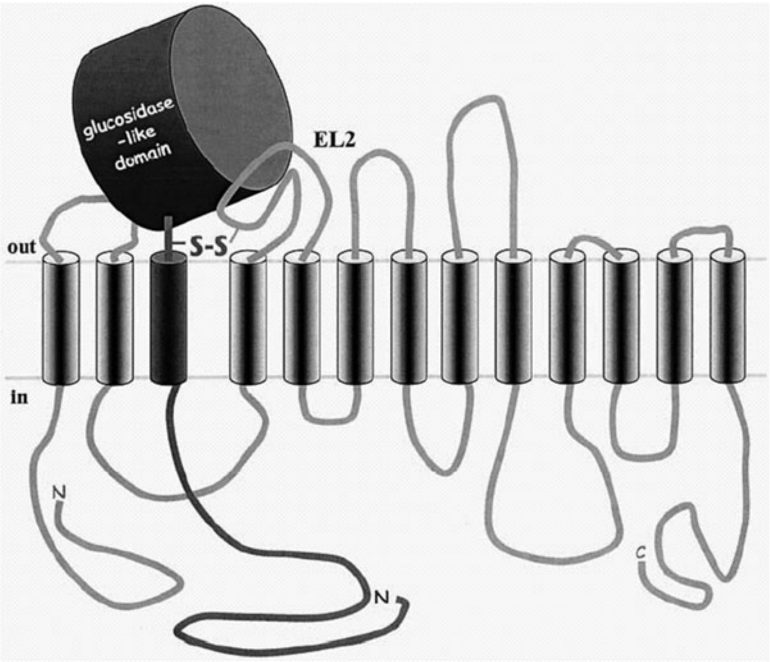

Fig. 3 Schematic representation of the heteromeric amino acid transporters (HAT). The heavy subunit of HAT (HSHAT; dark gray) is linked by a disulfide bridge to the corresponding light subunit of HAT (LSHAT; light gray). The cysteine residues involved in this bond (S-S) are located in an extracellular domain, following the transmembrane (TM) domain of HSHAT, and in the proposed extracellular loop 2 (EL2) of LSHAT. Loops and TM domains are simplified and not drawn to scale. See text for details. (Adapted with permission from ref. #38)

rearrangements [26, 34, 42]. Defective transport of cystine and dibasic amino acids has been demonstrated for many of these mutations when expressed in *Xenopus* oocytes [43]. The most commonly occurring mutation is methionine 467 to threonine (M467T), which causes a defect in trafficking to the plasma membrane [44, 45]. This trafficking defect, which has also been demonstrated for other rBAT mutations [46], is consistent with the proposed role of rBAT as a chaperon for the corresponding light subunit in the heteromeric amino acid transporter.

In 1997, Wartenfeld et al. [47] and Bisceglia et al. [48] demonstrated that cystinuria in other patients were linked to a locus on chromosome 19q13.1 (type B cystinuria). Subsequently, the International Cystinuria Consortium (ICC) [49] identified the gene *SLC7A9* which encodes the 487 amino acid protein $b^{0,+}$AT that belongs to the family of light subunits of amino acid transporters (LSHAT; Table 1). *SLC7A9* mutations were found in Spanish, Italian, North American, and Libyan-Jewish cystinuria patients [49, 50]. The G105R mutation is the most frequent *SLC7A9* mutation in the ICC cohort of patients [36]. The mutation in Jews of Libyan origin is valine 170 to methionine (V170M), which leads to complete loss of $b^{0,+}$AT amino acid uptake activity when cotransfected with rBAT in COS cells. To date, 118 different $b^{0,+}$AT mutations have been identified [26, 41].

Large-scale rearrangements represent between 17% and 21% of all found variants [42, 54]. The unexplained cases might be due to mutations outside the open reading frame of the *SLC7A9* and *SLC3A1* genes (intronic or promoter regions) or due to mutations in unidentified genes [26]. There may be mixed genotype groups such as AB, where individuals have one pathogenic variant in *SLC3A1* and one in *SLC7A9*, and AAB and BBA if there are more than two pathogenic variants pertaining to different genes. The ICC has reported that type A, type B, and type AB account for 38%, 47%, and 14% of cystinuria patients in their registry [34, 35].

Jaeken et al. described an autosomal-recessive disorder, hypotonia-cystinuria syndrome (MIM 606407), characterized by generalized hypotonia at birth, failure to thrive, growth retardation, minor facial dysmorphism, mild to moderate intellectual disability, and cystinuria type A [51]. The syndrome is caused by microdeletions of *SLC3A1* and a prolyl oligopeptidase-like gene (*PREPL*) which are adjacent on chromosome 2p21 [51]. Several similar disorders have been described in which type A cystinuria is associated with hypotonia-related syndromes due to the combined deletion of *SLC3A1* and contiguous genes [52].

Diagnosis and Clinical Features The diagnosis of cystinuria can be made by analysis of kidney stones, observation of cystine crystals in the urinary sediment, or detection of an abnormal excretion of cystine and dibasic amino acids in the urine in adults and children [53]. The simplest diagnostic test is the microscopic examination of the urinary sediment of a freshly voided morning urine [27]. The presence of typical flat hexagonal cystine crystals is diagnostic. The cyanide-nitroprusside test (CNT) is a rapid qualitative test that has been proposed as screening method for cystinuria. However, due to its low reproducibility and sensitivity and the use of hazardous and unstable reagents, most consider this test to be outdated [27]. The definite test is a measurement of urine cystine and dibasic amino acid concentration by ion exchange chromatography. The upper limits of normal are 18, 130, 16, and 22 mg/g creatinine for cystine, lysine, arginine, and ornithine, respectively [28]. While assessing for the possibility of cystinuria, it is important to exclude other conditions associated with increased urinary cystine excretion, including tubular immaturity in young infants, generalized aminoaciduria (Fanconi syndrome), and organic acidemias [27, 28].

Cystinuria usually presents with renal colic. In most patients, the first stone is detected during childhood or adolescence. Infection, hypertension, or renal failure may also develop [27]. Cystinuria occurs with equal frequency in males and females; one study reported that males were more severely affected [33], although other case series did not confirm that finding [54, 55]. Most patients have recurrent stone formation; however, not all patients with *SLC3A1* and *SLC7A9* mutations develop urinary calculi throughout their lives, and, in stone formers, age of onset of the lithiasis can vary substantially [26].

Cystine stones are radiopaque because of the density of the sulfur molecule and on a roentgenogram appear smooth. Occasionally, they form staghorn calculi. Cystine also may act as a nidus for calcium oxalate so that mixed stones may be found. Factors contributing to mixed stone formation in cystinuria include alkalinization of urine and urinary tract infections. Cystinuric patients who receive a kidney transplant have normal urinary cystine and dibasic amino acid excretion following transplantation [56].

Treatment The mechanisms involved in cystine kidney stone formation are related to the high concentration of cystine and its low solubility at normal urinary pH. Cystine crystalluria occurs when the cystine content of the urine exceeds 300 mg/L at pH 4.5–7. Cystine solubility increases sharply at a urine pH above 7 [27]. The major therapeutic approaches to cystinuria are designed to increase the solubility of cystine, reduce excretion of cystine, and convert cystine to more soluble compounds [26, 27]. Therapies used in the management of cystinuria include the following:

- Increased oral fluid intake to increase urine volume and cystine solubility. Because cystinuric patients excrete 0.5–1 g cystine/day, intake of 3–4 L is required to keep the urinary cystine concentration below 250 mg/L [53]. In children it is recommended to promote enough fluid intake to have a 24-h urine volume of more than 2 liters/1.73 m^2 [53]. Patients should develop a 24-h schedule for drinking and voiding, with particular attention to nighttime hours, when urine may become supersaturated with cystine. Rigid adherence to fluid therapy is effective in approximately 70% of patients [27].
- Oral alkali can further increase cystine solubility in the urine when combined with augmented fluid intake. A urine pH of 7.5–8 can be achieved by oral bicarbonate or citrate in divided daily doses. Because high sodium intake increases cystine excretion (see below), potassium citrate (60–80 mEq/day) is preferred [28]. Because urine alkalinization may result in formation of mixed calcium-containing stones, adherence to high fluid intake is crucial.
- Dietary therapy can reduce cystine production and excretion. Reduced methionine intake lowers cystine production, although intake should not be lower than the physiological requirement (i.e., 1200–1400 mg/day in adults) [54]. Protein restriction is not advisable in children as that may affect their growth. Urinary excretion of cystine and dibasic amino acids in cystinuric patients correlates with urinary sodium excretion [57]. Hence, dietary sodium restriction is also recommended for the treatment of cystinuria [26, 58].
- Pharmacologic therapy can increase cystine solubility and decrease cystine excretion. The sulfhydryl-binding compound D-penicillamine (β-dimethylcysteine) leads to the formation of the mixed disulfide penicillamine-cysteine following a disulfide exchange reaction. This mixed disulfide is far more water-soluble than cystine. Penicillamine, given at a maximum dosage of 1.2 g/24 h (20–30 mg/kg in children), is highly effective in reducing urinary cystine excretion. Unfortunately, penicillamine has serious side effects including rash, fever, arthralgia, nephrotic syndrome, pancytopenia, and loss of taste. Penicillamine also impairs pyridoxine metabolism and increases copper and zinc excretion in the urine. Mercaptopropionyl glycine (tiopronin; Thiola), another agent undergoing a disulfide exchange reaction, is as effective as D-penicillamine in the treatment of cystinuria. While some have suggested that serious adverse events are less common with tiopronin, a large recently published study showed that the incidence of adverse effects was similar for the former and penicillamine [55, 59]. Hence, cystine-binding drugs should be reserved for patients unresponsive to conservative management, and stepwise dosing is recommended [27].

Studies examining the efficacy of the angiotensin-converting enzyme inhibitor, captopril, and meso-1,3-dimercaptosuccinic acid

(DMSA) (both sulfhydryl compounds able to build highly soluble disulfides with cysteine) in cystinuria have yielded conflicting results [60, 61]. Hence, these agents are not recommended as therapeutic modalities in cystinuria. Finally, as recently suggested by Goodyer's group [41], cystinuria, like several other hereditary kidney diseases, could be amenable to therapy by a new class of aminoglycosides with increased translational readthrough of nonsense mutations and reduced toxicity. Cystinuria type A patients with homozygous nonsense mutations in *SLC3A1* are most likely to benefit from this potential therapy since even partial restoration of gene function might reduce urinary cystine to levels below the solubility threshold [41].

- Several urologic procedures have been used to treat cystine stones. Extracorporeal shock wave lithotripsy (ESWL), ureteroscopy (URS), or percutaneous nephrolithotomy (PCNL) are all options for treating cystine stones. Although cystine stones are often considered relatively ESWL-resistant, ESWL may be offered to cystinuria patients, including children, with previous treatment success or to avoid invasive procedures. When PCNL is considered, miniaturized techniques may offer equivalent stone clearance rates to that with standard PCNL but with reduced renal insult [53].

In summary, the mainstays for therapy in cystinuria include hydration, alkalinization of the urine, and dietary sodium restriction. Full compliance with this regimen results in significantly reduced urinary cystine excretion and good long-term prognosis in most patients. Pharmacologic treatment with sulfhydryl agents should be reserved for patients in whom conservative therapy fails. The use of increased translational readthrough in the treatment of cystinuria remains to be established. Urologic intervention is indicated in selected patients with severe obstructing stones.

Lysinuric Protein Intolerance (LPI) (Hyperdibasic Aminoaciduria Type II) Lysinuric protein intolerance is a rare autosomal-recessive disorder characterized by excessive urinary excretion of dibasic amino acids (especially lysine), normal cystine excretion, and poor intestinal absorption of dibasic amino acids [62, 63]. Plasma values of dibasic amino acids are low. The disease is most common in Finland, where the prevalence of the disease is 1:60,000 [62]. About 140 patients, Finish as well as non-Finish, have been described [62, 63, 64]. Homozygous patients have massive dibasic aminoaciduria as well as hyperammonemia after a protein load; heterozygotes have normal urinary amino acid excretion but impaired renal and intestinal transport of dibasic amino acids with increased protein loads. The clinical manifestations in subjects homozygotes for LPI often mimic urea cycle disorders, including having digestive and neurological signs and symptoms (hypotonia, lethargy, ataxia, seizure, and hyperammonemic coma after high protein intake). Malnutrition is often observed and is responsible for growth delay. Most patients also have cytopenia, hepatosplenomegaly, high ferritinemia, and hypertriglyceridemia attributed to chronic hemophagocytic lymphohistiocytosis [64, 65]. Pulmonary alveolar proteinosis is observed in up to 70% of the patients [66]. Osteopenia and severe osteoporosis sometimes leading to pathological fractures can occur.

The pathogenic mechanism of LPI appears to be a defective transport of dibasic amino acids in the basolateral membrane of renal and intestinal epithelial cells, resulting in impaired efflux from the cell to the interstitium [67, 68]. This has been confirmed by a measurement of fluxes in jejunal biopsy specimens from LPI patients [67] as well as by the observation that infusion of citrulline to these patients results in massive argininuria and ornithinuria [68]. Citrulline is reabsorbed from the tubular lumen by a neutral amino acid transport mechanism and is converted to arginine and ornithine in the renal cell. Impaired exit at the basolateral membrane results in backflux of accumulated arginine and ornithine across the brush-border membrane. The high-affinity, specific dibasic amino acid transporter y^+L is the protein affected in this disease (69, 70; Fig. 1). Because basolateral membrane transporters of epithelial cells and plasma membrane transporters of parenchymal cells are homologous carriers, it is not surprising that granulocytes [71] and cultured skin fibroblasts [72] from patients with LPI show impaired transport of dibasic amino acids. Erythrocytes from LPI patients, which do not have the y^+L system, have normal cationic amino acid transport.

It is presumed that the poor intestinal absorption and excessive renal loss of dibasic amino acids deprive hepatic cells of ornithine and arginine, which are necessary for urea production [62, 70]. This results in protein intolerance, hyperammonemia, and limited urea formation. These presumptions are supported by the observation that L-citrulline supplements improve protein tolerance in LPI patients [68]. L-citrulline, a metabolic precursor of ornithine and arginine, is absorbed in the intestine, enters the hepatic cell via neutral amino acid transport mechanisms, is metabolized in the liver to ornithine and arginine, and restores the pathway for ammonia disposal [62]. Several abnormalities seen in LPI patients including glomerular dysfunction [73], erythroblastophagia, and alveolar proteinosis [74] suggest that the immune system is deranged in some of these patients.

The molecular genetics of LPI has been elucidated. Linkage studies in Finnish and non-Finnish LPI families localized the gene associated with LPI to 14q11–13 [75, 76]; subsequently, Torrents et al. identified mutations in the *SLC7A7* gene as causative for LP1 [77]. Normally, y^+LAT-1 (*SLC7A7*), a member of the family of light subunits, combines with 4F2hc (*SLC3A2*), a member of the heavy subunit family, to form a heteromeric amino acid transporter (HAT) [35, 78] (Figs. 2 and 3). The 4F2hc/y^+LAT-1 transporter comprises the amino acid transport system y^+L that causes efflux of basic amino acids at the basolateral membrane of epithelial cells [45] (see Specificity and Classification of Amino Acid Transport Systems; Figs. 1 and 2). The heavy subunit, 4F2hc (*SLC3A2*), is essential for trafficking the transporter to the membrane, whereas the light subunit, y^+LAT-1 (*SLC7A7*), confers the transporter function [25, 37]. In 1999, two groups demonstrated that mutations in *SLC7A7* cause LPI in Finnish, Italian, and Spanish patients [79, 80]. To date, approximately 50 *SLC7A7* mutations, found along the entire *SLC7A7* gene, have been identified in LPI patients from different ethnic groups [70, 81]. Expression studies in *Xenopus* oocytes have shown that several *SLC7A7* LPI mutations result in y^+LAT-1 proteins that fail to dimerize with 4F2hc and reach the plasma membrane [82]. While 4F2hc (*SLC3A2*) is ubiquitously expressed, y^+LAT1 (*SLC7A7*) is primarily expressed in tissues affected in LPI including the kidney, small intestine, lung, and white blood cells [35, 77].

No LPI mutations have been identified in the *SLC3A2* gene, which suggests that these may be lethal [25]. Indeed, 4F2hc is responsible for the trafficking of at least six amino acid transporter light subunits [36], including y^+LAT-1, and mediates integrin signaling [83]. Finally, 4F2hc knockout in mice is lethal [84].

LPI has poor genotype/phenotype correlations. Finnish patients, who share the same founder mutation, have variable clinical pictures [70, 82]. Similarly, both interfamilial and intrafamilial phenotypic variability have been observed in Italian LPI patients carrying the same mutation [63]. This suggests that, in addition to *SLC7A7* mutations, currently unknown genetic modifiers have a role in the pathogenesis of LPI [69].

Therapy for LPI includes protein restriction to prevent hyperammonemia. In addition, oral citrulline supplements help correct the hepatic deficiency in ornithine and arginine, resulting in clinical improvement and catch-up growth [64].

Hyperdibasic Aminoaciduria Type I Hyperdibasic aminoaciduria type I (HDBA I) is an autosomal-dominant cationic aminoaciduria that has been described in two families with several heterozygous and a single homozygous patient [85, 86]. This disease is characterized by impaired renal reabsorption and intestinal absorption of the dibasic amino acids lysine, arginine, and ornithine, but not of cystine. Plasma values of dibasic amino acids are normal and patients have no protein intolerance or hyperammonemia. The single homozygous patient had mental retardation [86]. HDBA I heterozygotes have modest cationic aminoaciduria, whereas LPI heterozygotes have no hyperaminoaciduria. Some speculate that the brush-border, membrane-bound, high-capacity transporter for dibasic amino acids, which excludes cystine, is defective in this disease. The molecular identity of the transporter affected by this disease is unknown.

Isolated Lysinuria This disease was first reported by Omura et al. who described a single child with increased urinary excretion and impaired intestinal absorption of lysine, low plasma lysine levels, and normal renal and intestinal transport of ornithine, arginine, and cystine [87]. The patient did not have hyperammonemia but had poor overall growth and mental retardation, likely secondary to the deficient lysine. This case implies the existence of a selective transport system for lysine in the kidney and the intestine. Such a system has not yet been identified in physiologic or molecular studies.

Neutral Aminoaciduria

Three distinct disorders of neutral amino acid transport have been identified: Hartnup disorder, methioninuria, and histidinuria.

Hartnup Disease Hartnup disease, which may have afflicted Julius Caesar and his family [88], was first recognized in two siblings in England in 1956. This disease is characterized by intestinal malabsorption and massive urinary levels of the neutral monoamino monocarboxylic amino acids: alanine, serine, threonine, valine, leucine, isoleucine, phenylalanine, tyrosine, tryptophan, histidine, glutamine, and asparagine [89, 90]. Most patients also have increased excretion of indolic compounds that originate in the gut from bacterial degradation of tryptophan [91]. Transport of other neutral amino acids including cystine, imino acids, glycine, and β-amino acids is unaffected. The disease has autosomal-recessive inheritance and has an estimated incidence of 1:20,000 live births. Heterozygous carriers have normal urinary acid excretion under physiologic conditions. Clinical features in homozygous patients may include photosensitive rash, cerebellar ataxia, and a variety of psychiatric manifestations mimicking pellagra [89, 90]. The pellagra-like manifestations are primarily caused by intestinal malabsorption and urinary loss of tryptophan, an amino acid that is required for niacin synthesis. The diagnosis should be suspected in any patient with pellagra who has no history of niacin or nicotinamide deficiency and should be made by chromatographic analysis of the urine [89].

A defect in the broad-specificity neutral, α-amino acid transport mechanism in the renal and intestinal brush-border membrane is presumed to be the pathogenic mechanism underlying this disorder [16]. Several lines of evidence support the contention that the transport defect is localized to the brush-border membrane [16]. First, plasma amino acid response in patients with Hartnup disease was somewhat restored after oral feeding of free α-amino acids but not when α-amino acid dipeptides were given orally [92]. Dipeptides are presumed to be reabsorbed by a dipeptide-specific brush-border membrane transporter and hydrolyzed within the intestinal cell; the free amino acids can then exit the cell via an apparently nondefective basolateral membrane-bound carrier in these patients. Secondly, tryptophan transport is normal in various parenchymal cells from patients with Hartnup disease including leukocytes, placenta, and cultured skin fibroblasts [89]. As indicated earlier, amino acid transporters in plasma membranes of parenchymal cells are homologous to basolateral membrane transporters in epithelial cells, making it unlikely that basolateral amino acid transport is defective in Hartnup disease.

At a molecular level, the transport characteristics and the epithelial distribution of the Na^+-dependent neutral amino acid transport system B^o (see Specificity and Classification of Amino Acid Transport Systems; Table 1, Fig. 1) fit with defects in Hartnup disease being secondary to mutations in this transport system. In addition, Bröer's group identified SLC6A19 in the mouse (see Table 1) [93] as the gene most likely linked to Hartnup disease in humans. Indeed, in 2004, two groups cloned the human *SLC6A19* gene from chromosome 5p15 and found several mutations in this gene in British, Japanese, and Australian patients with Hartnup disease [94, 95]. To date, a total of 21 mutations have been identified causing Hartnup disease [90, 96]. Interestingly, most of the probands with Hartnup disease analyzed are compound heterozygotes for *SLC6A19* mutations [97].

The presence of alternative transport pathways for neutral amino acids in the renal tubule explains why the defect in the broad-specificity neutral amino acid transport in Hartnup disease results in only partial transport defects for some amino acids (e.g., phenylalanine) [16]. These alternative systems, as well as the oligopeptide-biased carriers in the kidney and intestine, are responsible for normal plasma amino acid levels and lack of symptoms in most patients [98]. Scriver et al. posit that Hartnup disease has multifactorial pathogenesis, and only patients with genetic mutations resulting in low plasma amino acid levels and impaired tryptophan metabolism develop symptoms [98]. Moreover, given the phenotypic heterogeneity of patients with Hartnup disorder [96], it is likely that other mutations (or polymorphisms) in other genes encoding for transport systems for neutral amino acids will be identified in the near future. Furthermore, transport and expression studies in *Xenopus* oocytes [99, 100] suggest that the differences in how mutant B^0AT1/SLC6A19 transporters associate with partner proteins collectrin (Tmem27) and angiotensin-converting enzyme 2 (ACE2) in the kidney or intestine, respectively, likely contribute to the phenotypic heterogeneity of human Hartnup disorder [90, 101].

Patients with Hartnup disease respond well to oral therapy with nicotinamide at 40–100 mg/day [90]. Also, oral administration of tryptophan ethylester, a lipid-soluble form of tryptophan, has been shown to increase serum tryptophan levels and reverse clinical symptoms in patients with Hartnup disease [102].

Methioninuria Methioninuria has been reported in two case reports of patients with isolated increased urinary excretion of methionine and its metabolic breakdown products [103, 104]. These patients had malodorous urine, edema, episodic hyperventilation, seizures, and mental retardation. The underlying defect appears to be abnormal transport of methionine in the kidney and in the intestine. Patients were noted to have high levels of α-hydroxybutyric acid, a bacterial degradation product of unabsorbed intestinal methionine, in the urine. This organic acid could be responsible for the neurologic manifestations observed in these patients. Low-methionine diet resulted in significant clinical improvement. While methionine shares a broad-spectrum amino acid transport system with other neutral amino acids, it is not hyperexcreted in Hartnup disease; this provides evidence that a specific transport pathway for methionine exists in renal and intestinal epithelium.

Histidinuria Isolated histidinuria has been reported in two siblings [105] and two other patients [106, 107]. All were severely mentally retarded. Investigations revealed impaired transport of histidine in the kidney and intestine. Parents of the two affected siblings had normal urinary histidine excretion under normal conditions, but hyperhistidinuria after an oral histidine load. The mode of inheritance of this disease is uncertain, but autosomal-recessive inheritance has been suggested [16]. Although *in vitro* studies have shown that the broad-specificity transporter of neutral amino acids is the major carrier for histidine, fractional excretion rates above 50% have been observed for this amino acid in Hartnup disease [16]; taken with the reports on isolated histidinuria, a specific histidine carrier likely operates in the renal tubule and the intestine.

Iminoaciduria and Glycinuria

Two disorders belong to this group of aminoacidurias: iminoglycinuria and isolated glycinuria.

Iminoglycinuria Iminoglycinuria is an autosomal-recessive membrane transport defect characterized by excretion of excessive amounts of proline, hydroxyproline, and glycine in the urine [108]. Iminoglycinuria is a benign condition with an estimated incidence of 1:15,000 live births [108, 109]. It has been postulated that the shared, brush-border membrane-bound, group-specific transport pathway for imino acids and glycine (PAT; see Specificity and Classification of Amino

Acid Transport Systems; Table 1, Fig. 1) is most likely defective in this condition [108, 110]. The selective glycine-specific (Gly) and imino acid-specific (Imino) transport systems are thought to be affected as well. However, differential function of the selective transporters could account for the normal plasma levels of glycine and imino acids occasionally observed in iminoglycinuria. In addition, immaturity of these selective transporters in normal infant tubules is responsible for neonatal physiologic iminoglycinuria [110]. The lack of function of the two selective transporters in infants with iminoglycinuria, who then also lack the shared transporters, leads to fractional excretion values for glycine and proline approaching 100%, which decline after the first months of life [16]. Defective intestinal transport of proline has been found in some patients with iminoglycinuria [108]. Together, the differential diagnosis of iminoglycinuria includes neonatal iminoglycinuria, Fanconi syndrome in which generalized aminoaciduria occurs, and hyperprolinemia, an inborn error of proline metabolism.

At a molecular level, iminoglycinuria appears to be a genetically and pathophysiologically heterogenous condition with several mutant alleles [16, 108], as is supported by several observations. First, obligate heterozygotes may have isolated hyperglycinuria or may have normal urinary amino acid excretion [111]. Second, some homozygous patients have an intestinal transport defect, while others do not. Third, a variant exists with normal transport maximum (Tm) for proline but with a defect affecting glycine transport capacity more than proline, indicating a K_m defect [112] (see below). In 2008, Bröer and colleagues found that combinations of mutations and polymorphisms in PAT2/*SLC36A2*, XT2/*SLC6A18*, and IMINO/*SLC6A20* (the molecular correlates of PAT, Gly, and Imino, respectively; Table 1) cause iminoglycinuria [113]. The major gene involved in patients that are homozygous for the disease is *SLC36A2*, whereas other patients have mutations and polymorphisms in the genes encoding *SLC6A18* and *SLC6A20* that result in variable renal or renal/intestinal phenotypes and/or in iminoglycinuria or glycinuria phenotypes [113].

Isolated Glycinuria Isolated glycinuria without iminoaciduria has been reported in two families [112, 114]. Some suggest that this condition results from mutations in the specific high-affinity carrier for glycine, namely, XT2/*SLC6A18*, which is expressed in the brush-border membrane of the late proximal tubule (Table 1) [16]. Others have suggested that hyperglycinuria represents a defect in the shared, imino acid-glycine transport system, PAT2/*SLC36A2*, affecting affinity rather than capacity of the system (K_m variant) [25, 113]. Because the condition appears to be inherited as an autosomal-dominant condition, it is also possible that these patients are heterozygotes for the iminoglycinuria allele. Glycinuria has also been reported in association with glycosuria, which is referred to as glycoglycinuria [115]. Together, the genetic defect underlying isolated glycinuria remains unclear.

Dicarboxylic Aminoaciduria

Dicarboxylic aminoaciduria, including selective urinary hyperexcretion of the acidic amino acids glutamate and aspartate, was first reported in two children [116, 117]. One of the children also had impaired intestinal absorption of these amino acids. One patient also developed hypoglycemia that corrected when treated with glutamate and aspartate [116]. This hypoglycemia likely resulted from impaired gluconeogenesis from reduced levels of these gluconeogenic amino acids. This condition is inherited in an autosomal-recessive fashion and appears to be mostly benign; screening in a French-Canadian population revealed a large number of healthy individuals with hyperdicarboxylic aminoaciduria and an incidence of 1: 35,000 live births [118].

Many have long thought that the pathogenic mechanism underlying the disease is a defect in the dicarboxylic amino acid transport system, X^-_{AG}, located in the renal brush-border membrane. Indeed, mutations in the human gene encoding the Na^+/H^+- and K^+-dependent glutamate/aspartate transporter, EAAC1 (*SLC1A1*; EAAT3), that is expressed in the luminal membrane of the late proximal tubule (Table 1; Fig. 1) were later shown to cause dicarboxylic aminoaciduria [119]. Surprisingly, although EAAC1 is widely expressed in the brain and functions as an important neurotransmitter, there is little evidence to suggest that dicarboxylic aminoaciduria leads to significant neural impairment in humans, other than an association with obsessive-compulsive behavior [25, 119]. Unexpectedly, decreased uptake of anionic amino acids has also been observed in cultured skin fibroblasts from affected patients [120].

β-Aminoaciduria

No inborn error of the luminal membrane-bound, Na^+- and Cl^--dependent transport systems that carry taurine/β-alanine (TAUT; *SLC6A6*) and betaine/GABA (BGT1; *SLC6A12*) has been reported in humans. Impaired taurine transport, however, has been detected in the inbred mouse strain C57BL/6J [121]. Studies using kidney slices [121] and isolated basolateral membrane vesicles [122] have localized the transport defect to the basolateral membrane of the proximal tubular epithelium. Similar to the defect in LPI, impaired taurine exit across the basolateral membrane and backflux from cell to lumen may underlie the hypertaurinuria observed in C57BL/6J mice [121, 122]. A transporter mediating transport of taurine across the basolateral membrane has yet to be identified.

Glycosuria

General Characteristics of Renal Glucose Transport

Under normal conditions, reabsorption of filtered glucose by the renal tubule is nearly 100% with less than 0.05% of the filtered glucose load appearing in human urine [123]; 90% of filtered glucose is reabsorbed in the proximal convoluted tubule, and the rest is reclaimed in the proximal straight tubule [123, 124]. No measurable glucose reabsorption occurs distal to the proximal tubule.

Reabsorption of glucose across the proximal tubular brush-border membrane occurs by an active, carrier-mediated, concentrative, Na^+-dependent transport process [123, 124]. The Na^+ electrochemical gradient driving glucose transport across the brush-border membrane is maintained by the basolateral membrane-bound Na^+-K^+-ATPase that transports Na^+ out and K^+ into the cell. Na^+-glucose cotransport across the luminal membrane is electrogenic-positive and phlorizin-sensitive. Glucose exit from the cell occurs by Na^+-independent, facilitated diffusion down the glucose concentration gradient [124]. This diffusional exit of glucose is mediated by a carrier that is distinct from that found at the luminal membrane surface (see later).

The mammalian kidney has a limited capacity to reabsorb D-glucose [123, 125]. As plasma glucose concentration progressively rises, glucose reabsorption increases linearly until reaching a maximum value (Fig. 4). Beyond this maximum rate of glucose reabsorption, further increases in filtered D-glucose load lead to glycosuria. As shown in Fig. 4, the glucose titration curve reveals the minimum threshold (F_{minG}) of glucose transport, defined as the filtered glucose load at which 1 mg of glucose per minute appears in the urine, and the tubular maximum for glucose reabsorption (Tm_G). Reported Tm_G values for glucose in human adults and children range between 260 and 350 mg/minute per 1.73 m^2 [126, 127], with even lower values in infants [127]. When corrected for the GFR (Tm/GFR), transport maximum value for glucose in humans at all ages is approximately 2.5 mg/mL [127]. The glucose titration curve (Fig. 4) is characterized by a splay, or a rounding of the curve, during the transition from virtually complete reabsorption of filtered D-glucose to complete excretion of excess glucose load. This deviation from the theoretical curve is explained by the nephron functional heterogeneity (the gradual progression from the first to the last nephron to saturate) as well as by the variation in affinity for glucose or K_m values between carriers [125].

Studies in isolated perfused tubules [128] and isolated BBMV from pars convoluta (S1 and S2 segments) and pars recta (S3 segment) of the proximal tubule demonstrate that the kinetic properties and stoichiometric relationships of D-glucose reabsorption change along the length of the nephron [129, 130]. These studies were the first to provide evidence for two Na^+-dependent

transport mechanisms, a low-affinity/high-capacity cotransport system in the early proximal tubule and a high-affinity/low-capacity system in the late proximal tubule. The Na^+-glucose coupling ratio was found to be 1:1 in the convoluted proximal tubule and 2:1 in the straight proximal tubule [129, 130]. The efficiency of a coupled carrier system increases with the power of the stoichiometry [124, 130]. Whereas the early proximal tubule glucose transporter is responsible for the reabsorption of the bulk of filtered D-glucose from the tubular lumen, the late proximal tubule glucose transporter is responsible for the removal of all but the last traces of glucose from the urine [130]. The arrangement of transporters in series along the proximal tubule enables the kidney to reabsorb glucose from the urine in a more energy-efficient mechanism than could be achieved by either of the cotransporters acting alone.

Molecular Biology of Na^+-Glucose Cotransporters

Considerable progress has been made in the past two decades in elucidating the molecular structure of membrane proteins responsible for sugar transport, including the Na^+-glucose cotransporter [123, 131, 132, 133]. Hediger et al. used expression cloning in *Xenopus* oocytes to clone and sequence the first ever identified Na^+-dependent D-glucose transporter from rabbit [21] and human [134] intestine. Subsequently, molecular analysis revealed that rabbit intestinal and renal Na^+-glucose cotransporters are nearly identical. The transporter was later termed SGLT1 and the gene encoding it, *SLC5A1* [131]. The Na^+-glucose cotransport proteins belong to the SLC5 family of sodium cotransport proteins. Included in the SLC5 family are 12 human proteins, of which 6 are Na^+-glucose cotransporters (SGLTs) that are expressed in the kidney and other organs [132, 133]. The SGLT1 (*SLC5A1*) transporter, the prototype of the SGLT group, consists of 664 amino acids and has 14 membrane-spanning domains. In humans, the SGLT1 gene maps to chromosome 22q11.2 [135]. Expression studies by Pajor et al. [136] and Lee et al. [137] have provided evidence that the renal Na^+-glucose cotransporter SGLT1 is the high-affinity/low-capacity transporter found predominantly in the straight proximal tubule (S3 segment). Stoichiometry studies were consistent with a Na^+-to-glucose coupling ratio of 2:1 [137]. The SGLT1 (*SLC5A1*) gene has been implicated in hereditary glucose-galactose malabsorption (see Hereditary Glycosuria).

A second, low-affinity Na^+-glucose cotransporter named SGLT2 (*SLC5A2*) was later isolated from rat and human kidney [138]. The amino acid sequence of SGLT2 is 59% identical to that of SGLT1. SGLT2 has a Na^+-glucose coupling ratio of 1:1 and is strongly expressed in proximal tubule early (S1 and S2) segments [138]. Human SGLT2 gene was mapped to chromosome 16p11.2 close to the centromere [139]. Clinical, physiologic, and molecular data indicate that the SGLT2 gene, *SLC5A2*, is responsible for familial renal glycosuria (see Hereditary Glycosuria).

Molecular Biology of Facilitative Glucose Transporters

Glucose concentrated inside tubular epithelial cells flows to the interstitium down its concentration gradient through facilitative glucose transporters located in the basolateral membrane [123, 140]. The basolateral membrane glucose transporters belong to the SLC2 family of Na^+-independent facilitative hexose transporters, which includes 14 glucose transporters GLUT1–14 [140, 141]. The human erythrocyte glucose transporter GLUT1 (*SLC2A1*) was the first facilitative glucose transporter to be cloned and sequenced. It has 12 membrane-spanning domains and is the most ubiquitously distributed among the various isoforms [140, 141]. Studies using specific anti-GLUT1 antibodies have detected this high-affinity transporter in the kidney [142, 143], in the basolateral membrane of cells of the proximal straight tubule (S3 segment). GLUT2 (*SLC2A2*), a low-affinity transporter, is the predominant facilitative glucose transporter in hepatocytes and in the basolateral membrane of intestinal and renal tubular cells [142, 143]. In the kidney, GLUT2 is present only in the basolateral membrane of cells in the proximal convoluted tubule (S1 and S2 segments) [142, 143]. *SLC2A2* has been identified as the mutated gene in Fanconi-Bickel syndrome (see Hereditary Glycosuria).

In summary, transepithelial glucose transport in the proximal tubule occurs by two different pairs of apical Na^+-dependent and basolateral Na^+-independent glucose transporters [123, 140] (Fig. 5). A luminal Na^+-dependent, low-affinity/high-capacity glucose transporter designated SGLT2/*SLC5A2* and a basolateral Na^+-independent, low-affinity GLUT2/*SLC2A2* are responsible for the bulk of glucose reabsorption in the early part of the proximal tubule. A luminal Na^+-dependent, high-affinity/low-capacity SGLT1/*SLC5A1*, coupled with the basolateral Na^+-independent, high-affinity GLUT1/*SLC2A1*, reabsorbs the remaining low concentration of glucose in the late part of the proximal tubule.

Hereditary Glycosuria

Familial Renal Glycosuria

Familial renal glycosuria (OMIM# 233100) is characterized by variable amounts of glucose excreted in the urine despite normal concentrations of blood glucose [144]. The renal defect is specific for glucose and there is no increase in the urinary excretion of other sugars. Renal glycosuria is a benign condition without symptoms or physical consequences except during pregnancy or prolonged starvation, when dehydration and ketosis may develop [144]. Metabolism, storage, and use of carbohydrates as well as insulin secretion are normal. Diagnosis usually is done on routine urine analysis often during well visits. The distinction between renal glycosuria and diabetes mellitus is made with a fasting blood glucose level and a glucose tolerance test. The inheritance pattern in renal glycosuria is usually autosomal recessive, although glycosuria has been noted in some heterozygotes, leading some investigators to postulate a dominant inheritance [144, 145]. Renal glycosuria is not associated with impaired D-glucose transport in the intestinal epithelium [126]. The underlying pathogenic mechanism appears to be an isolated, selective defect in proximal tubular glucose transport.

Familial renal glycosuria is a heterogenous condition. Analysis of renal titration curves for glucose reabsorption reveals two types of renal glycosuria [125, 144] (Fig. 4). In type A, or classic renal glycosuria, minimal glucose threshold (F_{minG}) and maximum rate of glucose reabsorption (Tm_G) are reduced. In type B, F_{minG} is reduced, while Tm_G is normal but has an increased splay. It has been suggested that the type A mutation reflects reduction in the capacity of the glucose transport system, which might arise from a uniform defect in all

nephrons, and type B reflects a decrease in the affinity of the transport system, which might also be a consequence of nephron heterogeneity [126, 146]. A third type of glycosuria, termed type O, was described by Oemar et al. [147]. In this rare latter condition, tubular reabsorption of glucose is virtually absent, and all glucose filtered is excreted in the urine.

Regarding genetics, in 2002, the SGLT2 gene, *SLC5A2*, was first established as the mutated gene in familial isolated glycosuria [148] (Fig. 5). Subsequent studies have found nearly 30 *SLC5A2* mutations in patients with familial renal glycosuria [133, 149, 150]. These include missense, nonsense, and frameshift mutations. Interestingly, some *SLC5A2* mutations may result in renal glycosuria accompanied by generalized aminoaciduria [151]. Renal glucose wasting associated with generalized aminoaciduria is also a feature of maturity-onset diabetes of the young type 3 (MODY 3) caused by a mutation in the hepatocyte nuclear factor-1 alpha (HNF-1α) gene [152]. HNF-1α acts as a regulator of both transcription of *SLC5A2* [153] and expression of collectrin, important for neutral amino acid transport [154] (see Hartnup Disease). Hence, mutations or polymorphisms in HNF-1α may explain the link between glycosuria and aminoaciduria observed together in some cases of hereditary renal glucosuria and in MODY 3.

Unlike isolated renal glycosuria, which is a benign condition, intestinal glucose-galactose malabsorption is a potentially lethal disease. Glucose-galactose malabsorption (OMIM# 182380) is an autosomal-recessive disease characterized by a neonatal onset of severe watery diarrhea that may result in death unless glucose and galactose are removed from the diet [144]. Studies using jejunal biopsy specimens from affected patients have demonstrated a defect in intestinal Na^+-dependent glucose transport [155]. In 1991, molecular genetic studies in two sisters afflicted with glucose-galactose malabsorption revealed a missense mutation that causes an amino acid change in residue 28 from aspartate to asparagine in the intestinal brush-border SGLT1 Na^+-glucose cotransporter [156]. Thus, glucose-galactose malabsorption was the first reported disease that is caused by a mutation in a membrane transport protein. To date, more than 40 mutations in SGLT1 have been identified in patients with glucose-galactose malabsorption [133]. Mutant proteins cause a marked reduction in Na^+-glucose transport activity, which, in most cases, is due to missorting of the protein to the cell surface [133, 144]. Patients with glucose-galactose malabsorption have a mild defect in renal tubular reabsorption of glucose, with normal Tm for glucose but decreased minimal threshold (F_{minG}) [144, 155]. In contrast, patients with renal glycosuria show no defect in intestinal D-glucose absorption. Together, these data revealed that the SGLT1 Na^+-glucose cotransporter affected in glucose-galactose malabsorption is shared between the intestine and the kidney, as previously suggested [136, 137] (see above), while the glucose transporter impaired in glycosuria is only present in the kidney.

In summary, the clinical, physiologic, and molecular data on renal glucose transport to date have now led to the following model of the pathogenesis of familial renal glycosuria [123, 133, 157, 158] (Fig. 5). Defects in the low-affinity/high-capacity, 1 Na^+/1 glucose cotransporter (SGLT2/*SLC5A2*) of the early proximal tubule, which reabsorbs most renal tubular glucose, produce type A or type O classic renal glycosuria but have no effect on glucose absorption in the intestine. Studies in SGLT2-deficient mice [159, 160] have confirmed that SGLT2 mediates the reabsorption of most filtered glucose molecules in the early proximal tubule. This mouse model mimics and explains the glycosuria in patients with SGLT2/*SLC5A2* mutations. In contrast, SGLT1/*SLC5A1*, the high-affinity/low-capacity, 2 Na^+/1 glucose cotransporter of the late proximal tubule, mediates residual glucose reabsorption in the renal tubule and, when defective as in glucose-galactose malabsorption, causes only mild type B renal glycosuria.

Fanconi-Bickel Syndrome

Mutations in the gene encoding GLUT2 (*SLC2A2*), the basolateral membrane-bound, facilitative glucose transporter of the proximal convoluted tubule, are associated with glycosuria in the Fanconi-Bickel syndrome (OMIM# 227810) [161, 162, 163] (Fig. 5). This autosomal-recessive disorder is characterized by hepatorenal glycogen accumulation, fasting hypoglycemia, impaired utilization of glucose and galactose, renal Fanconi syndrome, rickets, and markedly stunted growth [163, 164]. The renal glucose losses are due to transport defects for monosaccharides across the renal basolateral membrane. It is conceivable that this results in glucose accumulation in the cell and glycotoxicity leading to the generalized proximal tubulopathy. To date, approximately 70 different mutations in *SLC2A2* have been detected in patients with Fanconi-Bickel syndrome [164, 165]. The mutations in GLUT2/*SLC2A2* can lead to quite variable clinical and biochemical findings and different degrees of proximal tubular dysfunction [165, 166, 167]. Therapy for patients with Fanconi-Bickel syndrome is targeted toward symptoms and includes stabilization of glucose homeostasis, treatment of rickets, replacement of renal solute losses, and promotion of growth [163].

Abstract

Over the last decade, research in the field of genetic disorders resulting in hypophosphatemia has significantly broadened our understanding of phosphate metabolism. X-linked hypophosphatemia is the most common inherited form of rickets, which is caused by renal phosphate wasting. The common denominator for all types of rickets is hypophosphatemia, which leads to an insufficient supply of the mineral to the growing bone. Recent findings on disease mechanisms and the role of fibroblast growth factor 23 (FGF23) in hypophosphatemic diseases have opened up new therapeutic avenues such as FGF23 blockade. We will discuss

Introduction

The etiology of hypophosphatemic disorders has been elucidated over the last decade, although not all puzzles were solved. In 1937, Albright first reported on a patient with rickets and severe hypophosphatemia not responding to high doses of vitamin D. The term vitamin D-resistant rickets was coined, and later the disease was called X-linked hypophosphatemic rickets respective X-linked hypophosphatemia [1].

In recent years, several underlying genes have been identified in different forms of hypophosphatemic rickets [2]. Rickets is a disease of the growth plate, which is why only growing children are affected [3]. While rickets has historically been thought to be a disease of calcium and vitamin D metabolism, there is increasing evidence that rickets is caused by the insufficient availability of phosphate, which is required for normal bone metabolism [4]. In principle, a phosphate deficiency can be caused by inadequate absorption in the intestine or kidneys. The latter situation can be further divided into defects in the tubular reabsorption apparatus and abnormalities of circulating factors that regulate phosphate reabsorption [5]. The discovery of fibroblast growth factor 23 (FGF23) was a major breakthrough in our understanding of hypophosphatemic disorders. FGF23 is a member of the FGF family, which mediates the combined renal tubular defects in phosphate reabsorption and altered vitamin D metabolism observed in many forms of hypophosphatemic rickets including XLH [6].

Nowadays, specific disease-causing mutations in genes involved in the regulation of phosphate homeostasis can be identified in approximately 85% of familial or sporadic cases of hypophosphatemic rickets [7–10]. This chapter deals with the etiology, clinical presentation, differential diagnosis, and management of hypophosphatemic disorders due to a decrease in renal tubular phosphate reabsorption.

Phosphate Homeostasis

Inorganic phosphate (Pi) plays a major role in cellular metabolism and skeletal mineralization. It accounts for about 0.6 and 1% of body weight of a neonate and an adult, respectively. Approximately 85% of total body Pi content is deposited as hydroxyl-apatite [$Ca_5(PO_4)_3OH$] in the skeleton and the teeth, and 14% distributes within the intracellular compartment. Inorganic phosphate is heavily involved in multiple cellular processes including cell membrane function (phospholipids), energy metabolism (ATP), cell signaling (phosphorylation by kinases), and DNA- or RNA-biosynthesis (phosphorylated nucleotides). Only 1% of the total body Pi content is found as a soluble fraction in the extracellular compartment. It contributes to the acid-base buffering capacity of the plasma and of the urine. Thus, if in clinical practice the phosphate concentration in serum or urine is determined, only "the tip of the iceberg" is visible. In addition, circulatory Pi is the central mediator between bone, the parathyroid glands, the intestinal tract, and the kidneys, which are fine-tuned by numerous hormonal signals in order to keep the serum phosphate concentration within close limits.

In adults, skeletal growth is completed and a steady state condition can be assumed. In this case, the serum Pi concentration is determined by the balance between intestinal absorption of phosphate from the diet (16 mg/kg per day), bone-turnover of phosphate in the skeleton (3 mg/kg per day), and urinary phosphate excretion (16 mg/kg per day), (Fig. 1). In children and adolescents, the balance of Pi must be positive to meet the needs of skeletal growth and consolidation. A typical

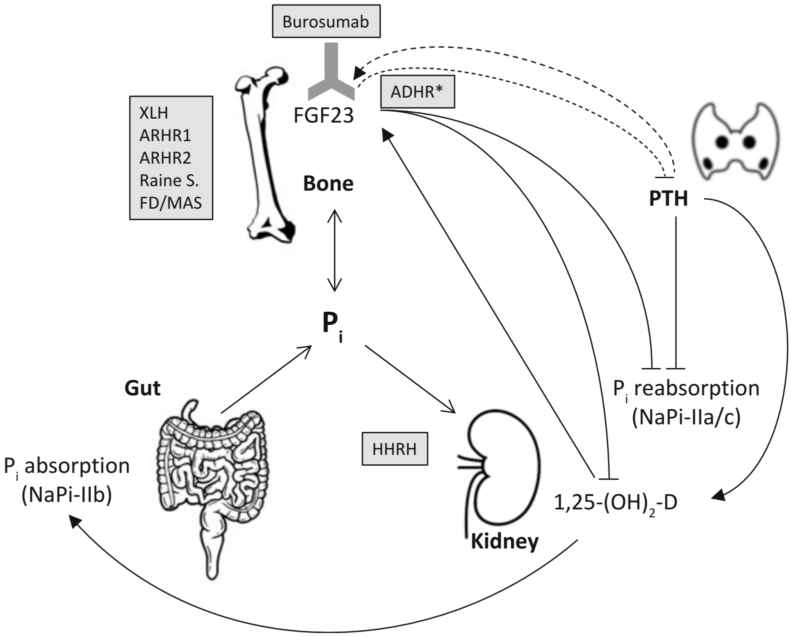

Fig. 1 Regulation of phosphate (P_i) homeostasis. FGF23 and PTH reduce renal tubular phosphate reabsorption via a decrease in apical expression of the sodium-phosphate cotransporters NaPi IIa and NaPi IIc. In contrast to FGF23, which inhibits 1,25(OH)$_2$D synthesis, PTH stimulates 1,25(OH)$_2$D production. 1,25(OH)$_2$D increases intestinal absorption of dietary P_i via increased expression of NaPi IIb and activates FGF23 production. PTH and FGF23 affect each other's production through a negative feedback loop that is not yet fully elucidated. The mode of action of the therapeutic antibody burosumab is indicated. Note, burosumab is currently licensed for treatment of XLH and tumor-induced osteomalacia (TIO), only. The sites of defect of the different genetic forms of hypophosphatemic disorders are given. XLH, X-linked hypophosphatemia; ARHR1/2, autosomal recessive hypophosphatemic rickets 1/2; Raine S., Raine syndrome; FD/MAS, Fibrous dysplasia/McCune-Albright syndrome; HHRH, hereditary hypophosphatemic rickets with hypercalciuria; ADHR, X-linked-dominant hypophosphatemic rickets. *FGF23 protein resistant to degradation

Western diet commonly provides plenty of alimentary Pi, most of which is provided by protein-rich foods such as meat, milk, and eggs. In contrast to plant-derived phosphate in the form of phytate (hexa-phospho-inosite), the animal-derived phosphate is easily absorbed by the intestine, where roughly two-thirds of the ingested phosphate is absorbed. Intestinal Pi absorption in infants is markedly higher than in adults due to the demands of a fast-growing skeleton and can exceed 90% of dietary intake. Absorbed Pi first distributes in the extracellular compartment and then equilibrates with the bone and intracellular compartment. Within the kidney, Pi is freely filtered via the glomerular capillaries and is reabsorbed mainly along the proximal nephrons according to the actual needs of the body. The majority of the transepithelial Pi transport in the intestine and the kidney is mediated by the type II family of sodium-coupled phosphate transporters, i.e., NaPi-IIa (NPT2a; *SLC34A1*), NaPi-IIb (NPT2b; *SLC34A2*), and NaPi-IIc (NPT2c; *SLC34A3*) [11]. NaPi-IIa is localized at the brush border of proximal tubular epithelial cells and accounts for roughly 90% of phosphate reabsorption by the kidneys. Reabsorption of the remaining 10% is accomplished by NaPi-IIc exclusively expressed along proximal tubules of deep nephrons. Their important role in Pi homeostasis is demonstrated by loss-of-function mutations resulting in renal phosphate wasting as noted in the rare syndrome of hypophosphatemic rickets with hypercalcemia (HHRH) [12].

In contrast to NaPi-IIa and NaPi-IIc, NaPi-IIb shows a broader expression pattern including pulmonary alveolar type II cells, where it participates in Pi uptake from the alveolar fluid for surfactant production. *SLC34A2* mutations cause pulmonary alveolar microlithiasis. Patients suffer from the deposition of calcium-phosphate crystals throughout the lungs [13]. In the intestine, NaPi-IIb is expressed in the brush border membrane of enterocytes and mediates absorption of phosphate from food.

Regulators of Phosphate Homeostasis

The amount of intestinal phosphate absorption is highly correlated to the dietary intake. Only 30% of intestinal Pi absorption occurs in a regulated, 1,25-dihydroxyvitamin D [1,25-$(OH)_2$D]-dependent manner. This poor regulation at the uptake level contrasts with the meticulous regulation of renal phosphate excretion. Proximal tubular reabsorption of phosphate, mainly via regulation of expression of NaPi-IIa and NaPi-IIc within proximal tubular brush border membranes, thus plays a key role in maintaining serum phosphate homeostasis. The amount of phosphate reabsorption by the kidneys is tightly regulated primarily by dietary Pi intake, parathyroid hormone (PTH), and fibroblast growth factor 23 (FGF23). Other factors such as insulin, growth hormone and its mediator insulin-like growth factor 1, and possibly FGF7 also affect renal phosphate handling, but their actions are less well understood [14].

Dietary Pi intake directly affects the amount of renal phosphate reabsorption. An increase or decrease in dietary Pi induces an increase or decrease in renal Pi excretion independent of vitamin D, PTH, or FGF23. Part of this effect could be explained by a phosphate-responsive element in the promoter of the *SLC34A1* gene [15].

Parathyroid hormone is an important hormonal regulator of proximal tubular Pi reabsorption. PTH synthesis and secretion are upregulated by low serum calcium and elevated serum phosphate levels, and downregulated by elevated serum calcium and 1,25$(OH)_2$D levels. Its binding to proximal tubular PTH receptors results in inhibition of NaPi-cotransport via mechanisms involving rapid clearance of NaPi-IIa from the tubular epithelial brush border membrane [16]. In addition, PTH also stimulates the synthesis of 1,25-$(OH)_2$D. The net effect of these actions is an increase in serum calcium levels and a decrease in serum phosphate levels.

Fibroblast Growth Factor 23 is a glycoprotein that is mainly synthesized in osteocytes and osteoblasts. The expression of FGF23 is induced by elevated serum phosphate and 1,25$(OH)_2$D levels. In the presence of Klotho, a membrane-bound protein with ß-glucuronidase activity, FGF23 binds with high affinity to the FGF receptor FGFR1 [14]. Klotho/FGFR1-mediated renal effects of FGF23 lead to an inhibition of proximal tubular Pi reabsorption and 1,25$(OH)_2$D synthesis. The net effect is thus a reduction in serum phosphate and 1,25-$(OH)_2$D levels, which may lead to hypocalcemia (Fig. 1).

Hypophosphatemic Disorders

Clinical, Biochemical, and Radiographic Manifestations Including Differential Diagnosis

Children with chronic hypophosphatemia experience growth retardation and rickets. Rickets is defined as an abnormality of differentiation and maturation of chondrocytes resulting in disorganized chondrocyte columns, and lack of mineralization of the growth plate. It is associated with decreased serum calcium and/or phosphate levels, leading primarily to widening and delayed mineralization of growth plates. Rickets is always associated with osteomalacia, i.e., a deficient mineralization of the bone matrix [17].

Bone deformities are the hallmark of rickets. Affected children present with progressive bowing of the femur and tibia. The site and type of deformity of the extremities depend upon the age of the child and the weight-bearing patterns of the limbs. Deformities of the forearms and posterior bowing of the distal tibia are more common in infants, whereas an exaggeration of the normal physiological bowing of the legs (genu varum) is a characteristic finding in the toddler who has started to walk. In walking children, valgus deformities of the legs or a windswept deformity (valgus deformity of one leg and varus deformity of the other) may be apparent. Deformities of the arms are virtually absent in hypophosphatemic rickets (Fig. 2). Palpable and visible knobby enlargements of the extremities of the long bones and osteochondral junctions (the "rachitic rosary") are the clinical manifestation of the disorganized hypertrophic growth plate. Because of the abnormal mineralization of the growth plate, growth is inevitably affected; in advanced forms, the growth may be stunted.

Severe rickets may also include delayed closure of the fontanelles, parietal and frontal bossing, craniotabes (soft skull bones), and craniosynostosis (Fig. 3A**).** Muscles are also affected with decreased muscle tone, leading to delayed achievement of motor milestones and a waddling gait [17–19]. In children, signs or severity of rickets should be assessed at each visit including measurement of intercondylar and/or intermalleolar distance (Fig. 4), as well as height, and growth velocity. Endodontic abscesses in teeth that seem intact are the major dental features of XLH in children (Fig. 3B**).** Usually, teeth are devoid of caries, history of trauma, or periodontal disease [20].

Radiologic changes of rickets are best visualized on radiographs at the growth plate of rapidly growing bones, i.e., the distal ulna, metaphyses above and below the knees, and at the ankles. Increased height of the physis is common to all forms of rickets. Widening of the epiphyseal plate and loss of definition of the zone of provisional calcification at the epiphyseal/metaphyseal interface are the early signs of rickets (Figure 5A). As the disease progresses, disorganization of the growth plate becomes more apparent with cupping, splaying, formation of cortical spurs, and stippling. The appearance of the epiphyseal bone centers may be delayed, or they may be small, osteopenic, and ill-defined. Deformities of the shafts of the long bones are often present. In severely affected adolescents, pathological fractures and Looser's zones, narrow radiolucent lines 2–5 mm in width with sclerotic borders also known as Milkman pseudofractures, may be noted.

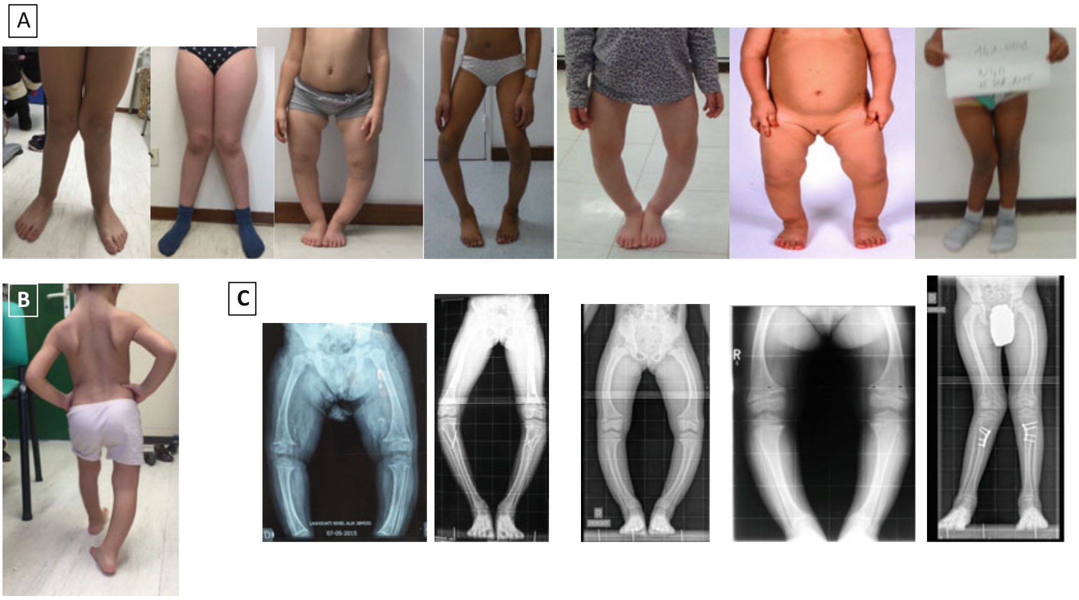

Fig. 2 Clinical and radiographic features of XLH. Photograph (upper **panel A**) and corresponding radiographs of the lower extremities (lower **panel C**) of children affected with X-linked hypophosphatemia (XLH). The patients show disproportionate short stature with different shapes of bowed legs (*genu valgum* [first two panels on the left], *genu varum*, and windswept [last panel on the right]). On **panel B**, the picture displays the typical waddling gait. The radiographs reveal severe leg bowing, partial fraying, and irregularity of the distal femoral and proximal tibial growth plates. Note the lack of bone resorption features on X-rays

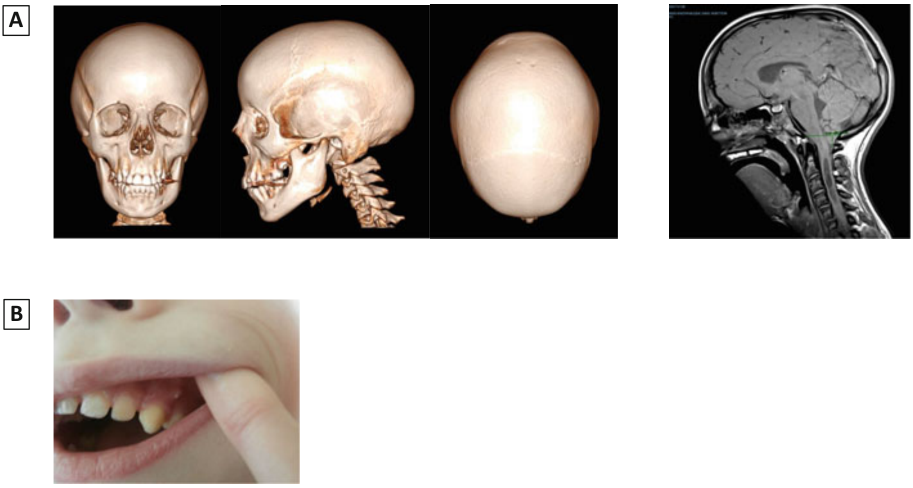

Fig. 3 Craniosynostosis in a child with XLH. (**a**) Typical pansynostosis; Chiari 1 malformation and syringomyelia. (**b**) Dental abscess on an apparently healthy tooth

Interestingly, in contrast to rickets due to an abnormal vitamin D intake or metabolism, where intracortical bone resorption with tunneling is a typical radiological finding, the cortical bone in children with hypophosphatemic rickets has a normal appearance or may even appear as thickened without signs of bone resorption [21, 22].

The rickets severity can be evaluated using the Rickets Severity Score (RSS), a quantitative scale developed for nutritional rickets by Tom Thacher. RSS is based on the degree of metaphyseal fraying and concavity, and the proportion of the growth plate affected at the wrists and knees [23].

MRI of the knee may be used as a tool to image the physis and feature the rickets in pediatric patients, allowing to minimize ionizing radiation in children and comply with keeping doses “as low as reasonably achievable” (ALARA) – or even “as low as diagnostically acceptable” (ALADA) (Figure 5B). MRI of the knees depicts rachitic changes in cartilage with an excellent resolution and three-dimensional acquisition, allowing a precise evaluation of physeal widening and transverse extent [21]. Radiographs and MRI of the knees allow precise monitoring of ricketic lesions during pharmacological treatment (Fig. 6).

Elevated alkaline phosphatase (ALP) activity confirms the diagnosis of rickets in patients with bone deformities and enlargement of the physes. It excludes all the differential diagnoses of abnormal metaphyses and bone deformities including Blount disease and metaphyseal dysplasia. It may also exclude hypophosphatasia in young patients with “ricketic” bone changes, yet elevated levels of calcium and/or phosphate. ALP levels tend to be moderately elevated in hypophosphatemic rickets (1–3 times the upper level of normal) in contrast with nutritional and hypocalcemic rickets with elevated PTH where ALP values are often greater (up to 10 ULN or more). Beside supporting the diagnosis of rickets, ALP is an excellent marker of disease activity and is, therefore, used as a tool to monitor treatment [18].

Low serum phosphate levels are found in almost all causes of rickets (Table 1**)** [4]. It is therefore of utmost importance to identify the pathological mechanism that leads to the chronic insufficient supply of phosphate, i.e., (i) high PTH activity, (ii) inadequate phosphate absorption from the gut, or (iii) renal phosphate wasting. The latter may be due to either tubular defects or high-circulating FGF23 levels (Fig. 7). The tubular reabsorption of phosphate (TRP) and the maximal tubular reabsorption of phosphate per glomerular filtration rate (TmP/GFR) are usually decreased, in all types of rickets, but are more pronounced in renal phosphate wasting types. An important pitfall to know is that in patients with insufficient intake or absorption of phosphate from the gut, TmP/GFR might be falsely low

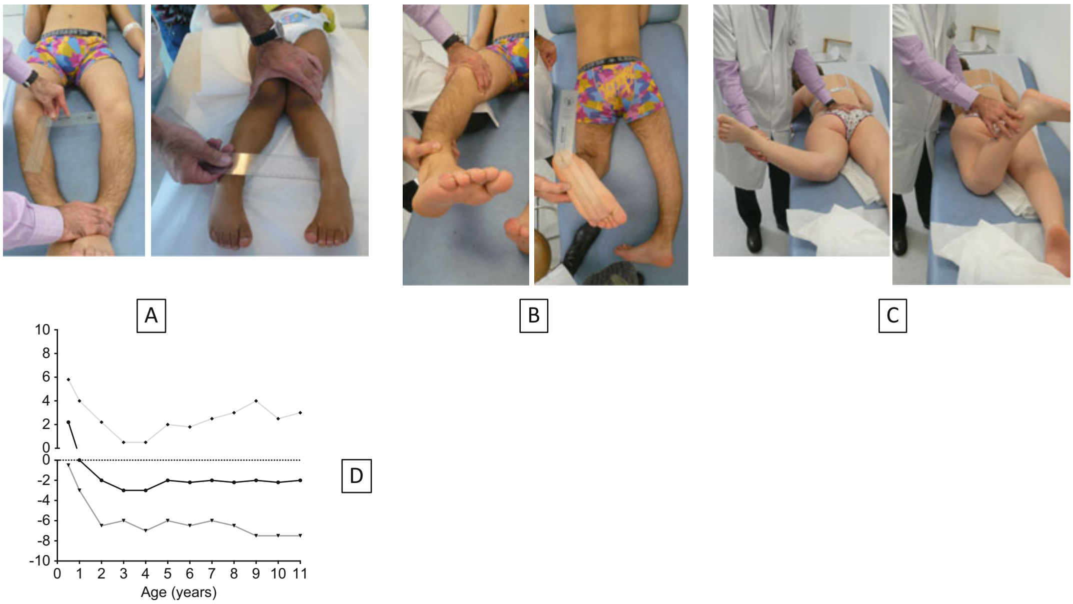

Fig. 4 Clinical assessment of bone deformities of lower limbs. (**a**) Illustration of the process of measuring the medial intermalleolar distance, (**b**) medial femoral intercondylar distance, and (**c**) medial tibial torsion and long bone torsion. (**d**) Physiological distance between knees and ankles in children. The upper part of the graph represents the 2 SD intercondylar distance (ICD, positive) and the lower part the 2 SD. intermalleolar distance (IMD, negative) and the mean values are represented in the middle of the graph. Note, measurement of IMD and ICD cannot replace a regular careful orthopedic assessment due to high complexity of leg deformities (e.g., torsion of limbs) in many patients [93]

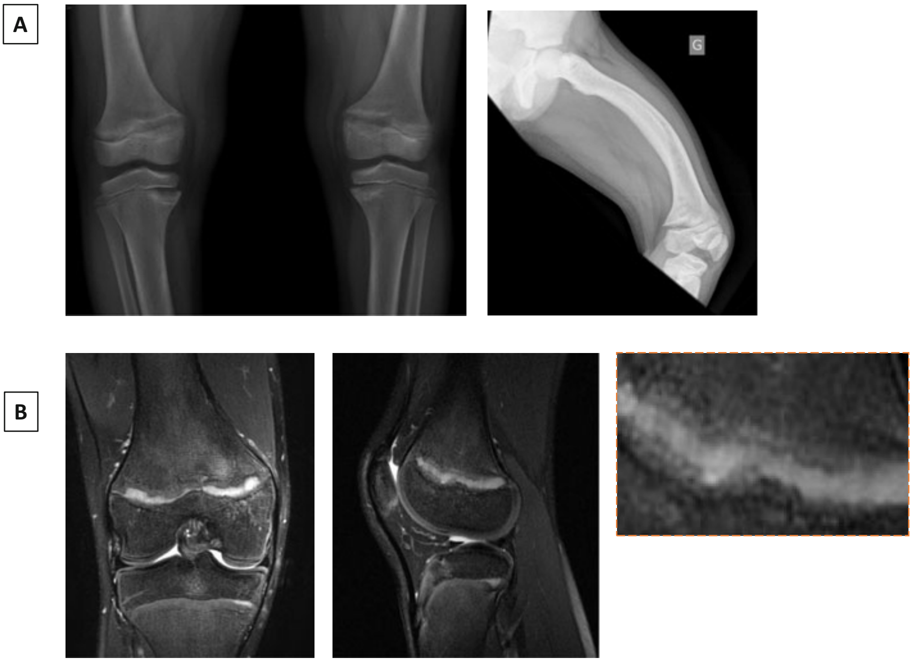

Fig. 5 Radiographic features of XLH. (**a**) Radiographs: Enlarged metaphyses with blurred limits; bowed femur and thick cortices in XLH. (**b**) Knee MRI. Increased physes spanning about 75% of the growth plate surface; the growth plate layers are visible on MRI

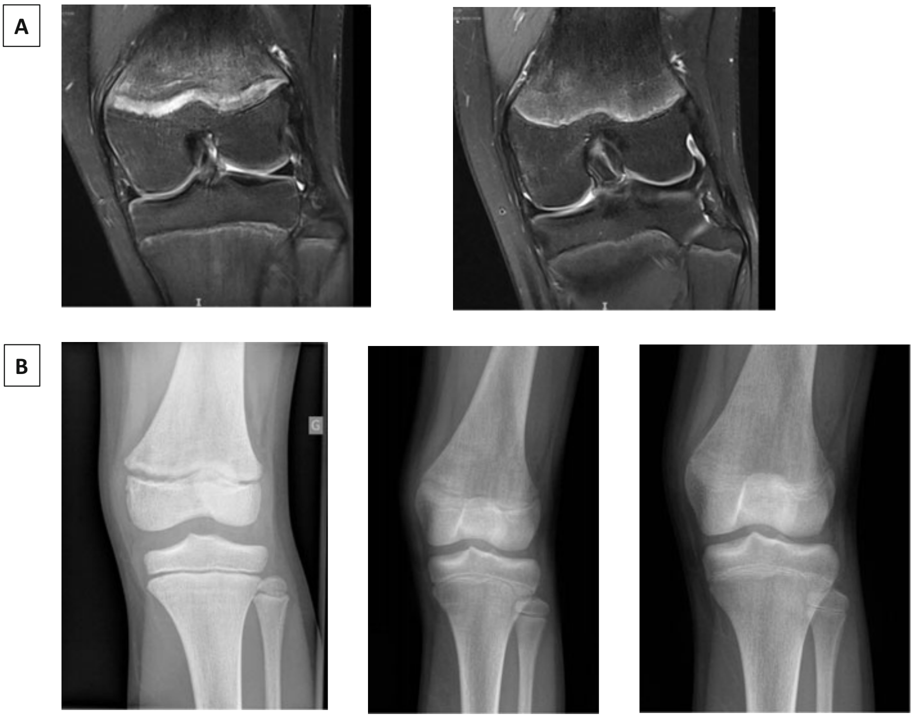

Fig. 6 Evolution of ricketic changes in children treated with burosumab. (**a**) Knee MRI. Increased physes spanning about 90% of the growth plate surface, in a child who received conventional therapy during 7 years; improvement after 1 year of burosumab on the left panel. (**b**) Radiographs: Enlarged metaphyses in a young girl (9 years old) treated with conventional therapy for 6 years; improvement after 2 and 3 years of burosumab therapy (middle and left panels)

when serum phosphate levels have not been restored to normal. This can usually be assumed in the presence of low urinary phosphate levels. In such cases, TmP/GFR should only be calculated after phosphate supplementation when serum and urine phosphate concentrations are raised.

The PTH concentrations are usually normal or modestly elevated in phosphopenic rickets. In most phosphopenic rickets, serum concentrations of 1,25(OH)2D may be low or inappropriately normal (in view of the ambient hypophosphatemia, which should trigger an increased production of the metabolite).

After exclusion of other causes of hypophosphatemia, and characterization of hypophosphatemia due to renal phosphate wasting, the measure of intact FGF23 contributes to the diagnosis of hypophosphatemic rickets (Fig. 7). Reference values for intact [24] and c-term FGF23 [25] in children are available but vary considerably according to the assay used. Therefore, in clinical practice the result in an individual patient should always be compared to reference values obtained using the same assay. FGF23 levels are also influenced by other factors, in particular phosphate intake and vitamin D therapy. Therefore, FGF23 levels are most informative in untreated patients. Finally, low normal FGF23 levels do not exclude FGF23-driven hypophosphatemia but should be interpreted as inappropriately normal in the setting of hypophosphatemia.

Table 1 summarizes the molecular genetic and biochemical characteristics of inherited or acquired causes of phosphopenic rickets in comparison to calcipenic rickets. The biochemical workup in children affected with hypophosphatemic rickets should initially include the measurement of phosphate, calcium, ionized calcium, creatinine, PTH, 25(OH)D, $1,25(OH)_2D$, FGF23, and an assessment of the renal tubular function, e.g., urinary potassium, sodium,

Fig. 7 Algorithm for the evaluation of the child with rickets presenting with hypophosphatemia. The differential diagnoses are based on the mechanisms leading to hypophosphatemia, namely high parathyroid hormone (PTH) activity, inadequate phosphate absorption from the gut, or renal phosphate wasting. The latter may be due to either primary tubular defects or high levels of circulating FGF23. Further details of individual entities can be found in Table 1; FGF-23, fibroblast growth factor 23 (Used with permission of Nature/Springer from Haffner et al. [18]

calcium, phosphate, creatinine, glucose, amino-acids, and beta2 microglobulin as well as calculation of TmP/GFR and TRP [18]. Reference values for serum and urine biomarkers used for assessment of renal hypophosphatemia are given in Table 2. Extended molecular genetic analysis may be required to establish diagnosis in unclear cases.

Hypophosphatemic Disorders with Increased FGF23 Activity

X-Linked Hypophosphatemia (*PHEX* Mutation)

XLH (OMIM #307800) is a dominant disorder with a prevalence of approximately 2/100,000 children. XLH is X-linked dominantly inherited, as it is caused by mutations in *PHEX*, located on chromosome Xp22 in ~90% of familial cases and ~ 70% of sporadic cases displaying a typical phenotype [8, 9]. The altered function of *PHEX* causes both the mineralization defect and the renal phenotypic abnormalities of XLH.

Clinical manifestations of XLH occur most often around the age of walking, despite an adequate vitamin D supplementation. In children, the primary clinical symptoms are rickets, including bone deformities, and impaired growth, dental abscesses, and craniosynostosis [18, 19, 22]. In the absence of diagnosis and/or treatment, patients may show extreme short stature with an adult height below −2 SD [26]. Tooth eruption is often delayed, but, when present, teeth display a normal enamel. The impaired mineralization of dentin is the cause of dental abscesses and early decay of lacteal and permanent teeth [27]. Many patients may have partial synostosis of the sagittal sutures leading to a dolichocephalic shape of the head. Type 1 Chiari malformation and syringomyelia are common complication of XLH mostly asymptomatic, and rarely featuring headaches and neck pain (Fig. 3) [19].

Conversion factor for calcium and ionized calcium: mg/dL × 0.25 = mmol/L

Conversion factor for phosphate: mg/dL × 0.323 = mmol/L

Conversion factor for intact PTH: pg/mL x 0.11 = pmol/L

Conversion factor for 25(OH)D: ng/mL x 2.5 = nmol/L

Conversion factor for 1,25(OH)2D: ng/L x 2.5 = pmol/L

NOTE. Metric Units x Conversion Factor = SI Units

TRP is calculated by entering the fasting urine and plasma concentrations, in the same concentration units, into the following equation TRP = 1- ((Up/Pp) x (Pcr/Ucr))

If the TRP is 86% or less, then TmP/GFR = TRP X Pp

If the TRP is greater than 86%, then TmP/GFR = 0.3 x TRP/ (1-(0.8 x TRP)) x Pp

XLH is characterized by elevated ALP, low serum phosphate (adjusted to age, see Table 1), phosphate wasting, and elevated levels of circulating FGF23. Normal FGF23 levels do not exclude XLH, since FGF23 levels depend on other factors, e.g., phosphate intake [28]. Average intact FGF23 levels in untreated Japanese pediatric XLH patients amounted to 84.5 ± 27.4 pg/ml (lowest, 38 pg/ml). The authors proposed a cutoff level to diagnose XLH of 30 pg/ml [29]. However, FGF23 values considerably differ depending on the assay used as well as other factors (vide supra).

On radiographs, the metaphyseal signs are those of common rickets. There are no signs of bone resorption, and usually, no radiolucency. As a consequence, the Thacher score of patients with hypophosphatemic rickets is usually graded below 3 on a scale of 10 [23].

The diagnosis of XLH is based on clinical, radiological, and biochemical findings. The x-linked inheritance strongly argues for the diagnosis. FGF23 is not available everywhere and is not fully mandatory for the diagnosis. Mutational analysis of the *PHEX* gene may also contribute to distinguish XLH from other forms of rickets.

ADHR (*FGF23* Mutation)

Autosomal-dominant hypophosphatemic rickets (ADHR) (OMIM#193100) is a rare disorder that was first described by Bianchine et al. in 1971 [30]. ADHR and XLH have marked clinical similarities but differ in their modes of inheritance. ADHR is caused by activating mutations of the *FGF23* gene. They result in a mutated protein resistant to cleavage by proteolytic activity, which in turn leads to elevated, circulating FGF23 levels [31]. The consequences of elevated FGF23 levels are renal phosphate wasting, hypophosphatemia, and inappropriately low levels of 1,25(OH)$_2$D. Important to note, the penetrance of ADHR is not complete, resulting in a highly variable phenotype and, consequently, variable symptomatology and biological findings. In contrast to XLH, patients suffering from ADHR usually become symptomatic after early childhood, even in in adolescence or even during adulthood. During childhood, the clinical symptoms are similar to that observed in XLH, i.e., rickets with bone deformities, disproportionately short stature, and dental abnormalities (abscesses) [32]. If patients become symptomatic after puberty, complications due to osteomalacia, e.g., weakness, fatigue, bone pain, and pseudofractures, are the major symptoms. XLHR adults present with symptoms similar to those with tumor-induced osteomalacia (TIO), as discussed below. Interestingly, some children show improvement of phosphate wasting during puberty [33]. Studies in ADHR mice and humans suggest that iron status is an important regulator of FGF23-metabolic pathways [33–35]. The onset of ADHR is probably the product of gene-environment interactions. In ADHR patients' serum, iron was negatively associated with both C-terminal FGF23 and intact FGF23 plasma levels. Similarly, a negative association between serum iron and C-terminal FGF23 was observed in healthy subjects, suggesting increased expression and cleavage of FGF23 in the setting of a low iron status. In line with this observation, a recent study in iron-deficient adult ADHR patients demonstrated normalization of both, serum FGF23 and phosphate levels by oral iron repletion [36]. Therefore, the standard approach to ADHR patients should also include recognition and management of iron deficiency.

ARHR (1, *DMP1* Mutation; 2, *ENPP1* Mutation)

The finding of hypophosphatemic rickets in consanguineous kindreds suggested an autosomal recessive form of hypophosphatemia (ARHR) [37]. The clinical presentation is similar to those of XLH patients including elevated FGF23 serum levels, renal phosphate wasting, and inappropriately normal levels of 1,25(OH)$_2$D. One difference is, however, that patients with ARHR show a relatively high bone density of the vertebral bodies on X-rays. ARHR is either due to mutations in the *DMP1* gene encoding for dentin matrix acidic phosphoprotein 1 (ARHR1) or to mutations in the *ENPP1* gene encoding for ectonucleotide pyrophosphatase/phosphodiesterase 1 (ARHR2) [38–41]. DMP1 is a member of the short integrin-binding ligand interacting N-linked glycoprotein (SIBLING) family of skeletal matrix proteins and is highly expressed in mineralized tissues, e.g., in osteoblasts and osteocytes. It is an important regulator of development of bone, cartilage, and teeth. How mutations in *DMP1* result in elevated FGF23 serum levels in ADHR1 patients is largely elusive. Levi-Litan et al. identified an inactivating mutation in the *ENPP1* gene (later named ARHR2) that caused ARHR in a Bedouin family [41]. ENPP1 is a cell surface protein that catalyzes phosphoester cleavage of adenosine triphosphate, generating the mineralization inhibitor pyrophosphate. Mutations in *ENPP1* were initially reported in patients with infantile arterial calcifications [42]. There is a high phenotypic heterogenity, and the clinical presentations may markedly differ in patients displaying the same biallelic *ENPP1* pathogenic variants including enthesopathy and primary hyperparathyroidism [43]. How inactivating *ENPP1* gene mutations result in increased FGF23 synthesis from bone is unknown.

Raine Syndrome Associated *FAM20C* Mutation

Raine syndrome (OMIM#611061) is an ultrarare disease caused by biallelic loss of function mutations in FAM20C. FAM20C is a key-regulator of osteoblasts/osteocytes; it also promotes FGF23 cleavage. The disease is characterized by generalized osteosclerosis, craniofacial anomalies including hypoplastic nose, midface hypoplasia, exophthalmos, intracranial calcifications, sensorineural hearing loss, developmental delay, epilepsy, large fontanelle, and amelogenesis imperfecta. Patients may display from a mild phenotype with hypophosphatemia and renal phosphate wasting due to elevated FGF23, to severe and lethal dysmorphic features [44].

Tumor-Induced Osteomalacia and Tumor-Induced Rickets (TIO)

Tumor-induced osteomalacia (TIO) is a rare acquired cause of hypophosphatemia and phosphate wasting. It is caused by the excessive production of phosphaturic factors including FGF23 by benign tumors, slowly growing, characterized as polymorphous neoplasms made of mixed connective tissue. These tumors are often small and difficult to localize through conventional imaging techniques. TIO occurs in adults, rarely in adolescents or children. There is no familial or personal history of rickets, and patients present with fractures, bone pain, fatigue, muscular insufficiency, hypocalcemia, hypophosphatemia, and high levels of FGF23. In comparison with XLH, mean phosphate and FGF23 levels are dramatically lower and higher in patients with TIO [36, 45, 46]. Normalization of phosphate homeostasis and osteomalacia occurs after the surgical removal of tumors; as surgery is sometime not possible, therapies aiming at lowering FGF23 levels and actions allow an improvement in phosphate level, renal tubular reabsorption of phosphate, muscular function, and quality of life of affected patients [47].

Hypophosphatemic Rickets and Hyperparathyroidism

In one patient with hypophosphatemic rickets, there were skeletal abnormalities and hyperparathyroidism due to parathyroid hyperplasia a de novo translocation with a breakpoint adjacent to α-Klotho, a factor known to regulate FGF signaling. In this patient, plasma α-Klotho and FGF23 levels were markedly elevated [48].

Fibrous Dysplasia (FD), McCune-Albright Syndrome (MAS), and Epidermal Neavi

Rickets occurs sometimes in patients with fibrous dysplasia (FD) due to activating mutations in GNAS observed in McCune-Albright syndrome. Briefly, in FD tissue, increased production and cleavage of FGF23 occurs. The degree of FGF23 overproduction correlates with the volume of FD lesions, i.e., disease severity and skeletal burden. Hypophosphatemia is usually mild and associated with phosphate wasting. However, the clinical consequences of FGF23-mediated hypophosphatemia may include earlier onset of bone features, increased risk of fractures, and FD-related bone pain. The evolution is peculiar as it may resolve as patients become older, likely reflecting the decline in the number of mutated stromal cells and the tendency of FD histologic features to improve over time [49].

Rarely, elevated serum FGF23 levels are found in association with mosaic cutaneous disorders that affect large proportions of the skin and appear in patterns corresponding to the migration of ectodermal progenitors. These disorders are named Epidermal nevi and congenital melanocytic nevi (EN and CMN) as well as Schimmelpenning–Feuerstein–Mims syndrome. The wide distribution of involved tissues and the appearance of multiple segmental skin and bone lesions are compatible with early embryonic somatic mutations. Indeed, in affected patients, exome sequencing of blood, dysplastic bone, and affected skin tissue identified somatic activating mutations of *HRAS* or *NRAS*. Elevated serum FGF23 is therefore the consequence of the somatic activating RAS mutation in bone [50].

Hypophosphatemic Disorders with Normal or Suppressed FGF23 Activity

HHRH (*SLC34A3* Mutation)

This important differential diagnosis to XLH was first described by 1985 Tieder et al. in 1985 reporting on an unusual case of hypophosphatemic rickets in a consanguineous Bedouin tribe [51]. In contrast to XLH, in HHRH (OMIM#241530) hypophosphatemia and phosphate wasting are associated with elevated 1,25(OH)$_2$D serum levels resulting in hypercalciuria and suppressed PTH plasma concentrations. The disorder was later shown to be caused by mutations in the *SLC34A3* gene encoding for the NaPi-IIc renal phosphate cotransporter in the proximal tubule, and many more patients were identified with different ethnicities from all over the world [52]. All so far reported mutations are loss-of-function mutations and, most likely, result in diminished renal phosphate absorption through decreasing the apical membrane expression of NaPi-IIc or the uncoupling of sodium-phosphate cotransport in the proximal tubule [52]. Thus, in contrast to XLH and ADHR, hypophosphatemia is not due to enhanced FGF23 serum levels in HHRH. The physiological consequence of the body facing hypophosphatemia is to increase 1,25(OH)$_2$D levels in order to enhance intestinal calcium absorption and suppress PTH levels. Unfortunately, this results in hypercalciuria promoting the development of nephrocalcinosis and nephrolithiasis. Milder forms may be underdiagnosed, and therefore, careful evaluation of urinary calcium excretion before and during medical treatment is strongly recommended in all patients with hypophosphatemic rickets, especially in those without a proven underlying genetic cause [53].

Hypophosphatemia and Nephrocalcinosis (*SLC34A1* Mutation, OMIM#612286)

The *SLC34A1* gene is located on chromosome 5q34 encoding for the NaPi-IIa renal phosphate cotransporter in the proximal tubule. *SLC34A1* mutations may result in a wide clinical phenotype including infantile hypercalcemia, kidney stones, and rickets, all of which are associated with reduced serum phosphate levels [54, 55].

Osteoglophonic Dysplasia (OMIM#166250)

Patients with mutations of FGFR1 (Fibroblast growth factor receptor 1) causing ligand-independent activation of the receptor have been found in osteoglophonic dysplasia. OGD is a rare disease characterized by craniosynostosis, facial dysmorphism, failure of tooth eruption, and variable short stature; some patients, but not all, develop hypophosphatemic rickets secondary to upregulated bony FGF23 secretion hence elevated FGF23 levels [56, 57].

Nephrolithiasis and Osteoporosis Associated with Hypophosphatemia

Two different heterozygous mutations (A48P and V147M) in *NPT2a*, a gene encoding a sodium-dependent phosphate transporter, were reported in patients presenting with urolithiasis or osteoporosis and persistent hypophosphatemia due to decreased tubular phosphate reabsorption [54, 58].

Fanconi Syndrome

De Toni Debré Fanconi syndrome is characterized by generalized proximal tubular dysfunction with impaired ability to absorb water, phosphate, glucose, urate, amino acids, and low-molecular weight proteins. Other common features include increased excretion of sodium, potassium, calcium, and bicarbonate. Clinical consequences result mainly from hypophosphatemia and metabolic acidosis, i.e., rickets and osteomalacia. The syndrome may be due to both genetic defects and acquired disorders with nephropathic cystinosis being the most common cause (see chap. XX). In the latter, FGF23 levels are inadequately low despite progressive CKD due to persistent hypophosphatemia [24].

Iatrogenic Phosphate Wasting

Low phosphate, decreased phosphate tubular reabsorption rate, and TmP/GFR have been firmly associated with exposition to certain chemotherapies such as cisplatin and ifosfamide [59]. This rarely results in clinical consequences; despite a significant reduction in tubular threshold for phosphate in ~25% of the children, hypophosphatemia is present only in ~1% [60]. Other drugs may also impair the renal tubular function inducing tubulopathy of variable severity; Fanconi syndrome and phosphate wasting have been described in patients receiving tenofovir or other protease inhibitors [61].

Treatment of XLH

The objective of the treatment is to heal rickets, restore the lower limbs shape, and improve growth, bone and teeth mineralization, and muscular function. A multidisciplinary approach is therefore mandatory to prevent the development of endocrine, orthopedic, rheumatologic, and renal complications. Disease management encompasses social aspects, patient/family education and support [17, 18].

Phosphate and Active Vitamin D Metabolites (Children and Adults)

In Children

Vitamin D analogs (alfacalcidol or calcitriol) and phosphate supplements through multiple daily dosing are used to counteract the calcitriol deficiency secondary to the increased FGF23 concentrations, and to compensate for renal phosphate wasting. Doses vary from 10–80 ng/kg/day of calcitriol and 30–60 mg/kg/day of elemental phosphorus. The efficacy of treatment should be regularly assessed through the measurement of ALP, physical measures of limb deformities, evaluation of the function through 6-minute walk test or POSNA, and PODCI subscales of height and growth velocity.

The recommended starting dose of phosphate based on elemental phosphorus is 20–60 mg/kg/day (0.7–2.0 mmol/kg per day) in infants and preschool children, which should be adjusted according to the improvements of rickets, growth, and ALP and PTH levels [18]. The recommended starting dose of calcitriol and alfacalcidiol is 20–30 ng/kg body weight and 30–50 ng/kg body weight daily, respectively. Alternatively, treatment may be started empirically at 0,5 μg daily of calcitriol or 1 μg daily of alfacalcidiol in patients aged above 12 months and adjusted on the basis of clinical and biochemical response. In addition, supplementation with native vitamin D is recommended in case of vitamin D deficiency.

This therapy has demonstrated its efficacy as it leads to a decrease in ALP to the upper limit of normal in ~1 year, an improvement in bone deformity, bone pain and gait in 30–60% of patients, an improvement in growth velocity of ~1 standard deviation, a significant improvement of dentin mineralization, and therefore a decrease of teeth abscesses and oral complications in affected children. It was clearly shown that early treatment initiation and longer duration of treatment are associated with better outcomes.

Phosphate and FGF23 levels, TmP/GFR or tubular reabsorption rate of phosphate, do not reflect treatment efficacy and should therefore not be used to guide treatment with phosphate and active vitamin D.

Long-term treatment with vitamin D analogs and phosphate supplements is associated with an increased incidence of nephrocalcinosis and/or urolithiasis, elevated levels of PTH, and sometimes secondary hyperparathyroidism. Therefore, safety should be considered at each evaluation by measuring serum levels of calcium and PTH, urinary calcium excretion, and renal ultrasound [18]. Other complications may occur during the course of treatment including insufficient improvement of bone shape leading to iterative corrective surgeries of lower limbs, impaired muscle function, craniosynostosis, and neurological features, e.g., Chiari 1 and syringomyelia, hearing problems, enthesopathy, chronic pain, and asthenia [6, 19, 62].

In Adults

Data show that, in adults, treatment may prevent or limit the consequences of chronic phosphate wasting such as osteomalacia-related fractures and pseudofractures, muscle impairment as well as dental problems.

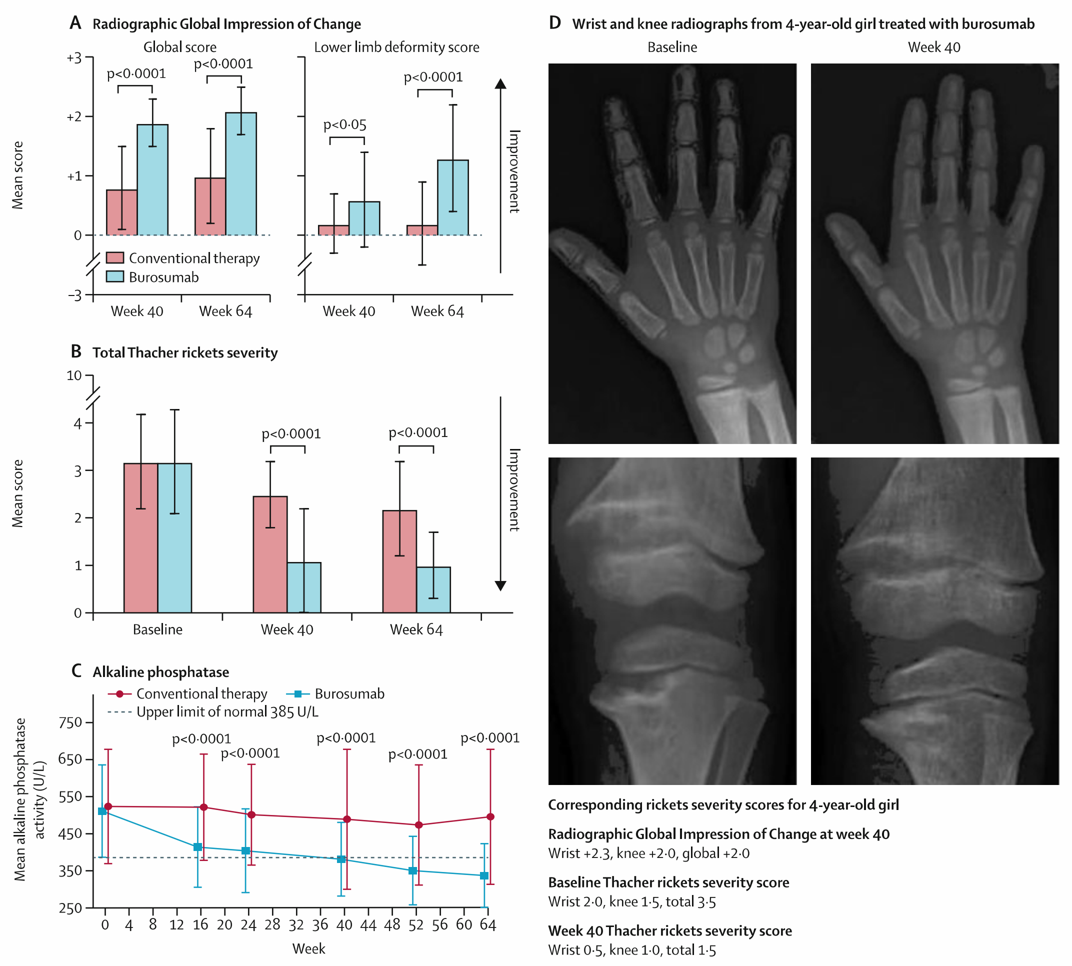
Oral phosphate salts and active vitamin D analogs are prescribed in symptomatic adults to reduce bone pain and improve osteomalacia, muscle strength, and physical function. Spontaneous insufficiency fractures are more likely to heal faster with therapy. It is also recommended before and after surgical orthopedic or dental interventions to promote bone mineralization. The treatment does not prevent the occurrence of enthesopathy and does not modify osteoarthrosis-related pain.

In asymptomatic patients, treatment to prevent long-term consequences of chronic hypophosphatemia should be weighed with the potential side effects such as hyperparathyroidism and nephrocalcinosis. However, it seems appropriate during pregnancy, lactation, and menopause, conditions associated with an increased calcium and phosphate demands.

Oral phosphate salts are given usually at 750–1600 mg/day (based on elemental phosphorus) in three to four doses; they should be avoided in patients with increased levels of PTH. In addition, active vitamin D analogs are given to improve bone mineralization, including unalfacalcidiol 0.75–1.5 μg once daily or calcitriol 0.75–1.0 μg twice daily. 25OHD deficiency should be corrected [18, 63].

Burosumab (Children and Adults)

Since 2018, the efficacy and safety of burosumab treatment was investigated in three clinical trials in children with XLH [64–66]. Two open-label uncontrolled trials testing burosumab in a total of 65 children aged 1–12 years with severe XLH demonstrated that in the short term (12–16 months) burosumab resulted in the following outcomes: a significant increase in TmP/GFR and consequently raised serum phosphate levels into the lower end of the normal range, with increased (normalized) 1,25(OH)$_2$ vitamin D levels; a significant reduction in the severity of rickets (as measured by the Rickets Severity Score (RSS) and the Radiographic Global Impression of Change (RGI-C)); a significant improvement in physical ability (as measured by walking distance in the Six Minute Walk Test); and a significant reduction in patient-reported pain and functional disability (as measured by the use of the Pediatric Orthopedic Society of North America Outcomes Data Collection Instrument) [64, 65]. Recently, a direct comparison between burosumab and conventional treatment was investigated in an open-label phase 3 trial including 61 children aged 1–12 and lasted 64 weeks [66–71]. The primary outcome analysis at 40 weeks showed that children treated with burosumab had significantly greater improvement in RGI-C and RSS than did patients in the conventional therapy group (Fig. 8 and 6**)**. Likewise, biochemical parameters such as ALP and serum phosphate levels were also rapidly normalized during burosumab treatment. The most common adverse reactions observed with burosumab were injection site reactions, headache and pain in the extremities. Two-weekly doses were superior to four-weekly doses with respect to normalization of serum levels of phosphate and radiological improvement of rickets. Conventional treatment should be stopped at least 1 week before the start of burosumab therapy for washout and to prove that fasting serum phosphate levels are below the normal reference for age. Supplementation with native vitamin D may be continued in patients under burosumab treatment.



Corresponding rickets severity scores for 4-year-old girl

Radiographic Global Impression of Change at week 40

Week 40 Thacher rickets severity score
Wrist 0·5, knee 1·0, total 1·5

Fig. 8 Improvements in rickets severity in children on burosumab versus conventional therapy with phosphate and active vitamin D metabolites. Data in panels A, B, and C are reported as mean (SD). p values are based on the comparison between treatment groups in the least squares mean change from baseline, using the ANCOVA model for the week 40 Radiographic Global Impression of Change global score and week 40 Thacher rickets severity score assessments, and the generalized estimating equation model for alkaline phosphatase assessments, lower limb deformity assessments, and week 64 rickets assessments. The upper limit of normal for alkaline phosphatase varies by age and sex: girls aged 1–4 years 317 U/L, 4–7 years 297 U/L, 7–10 years 325 U/L, and 10–15 years 300 U/L; boys aged 1–4 years 383 U/L, 4–7 years 345 U/L, 7–10 years 309 U/L, and 10–15 years 385 U/L. These ranges were provided by Covance laboratories. Radiographs in panel D show improvement in rickets with burosumab in a 4-year-old girl who previously received conventional therapy for approximately 26 months (Used with permission of Elsevier from Imel et al. [66]

Two open-label, uncontrolled trials and one randomized, double blind, placebo-controlled study (including a total of 176 patients) have investigated burosumab in adult XLH patients, and the majority presented with skeletal pain associated with XLH and/or osteomalacia [67–71]. Four-weekly doses of burosumab given over periods of 4–12 months were associated with the following outcomes: significantly increased TmP/GFR and consequently raised serum levels of phosphate into the lower normal range and increased (normalized) 1,25 $(OH)_2$ vitamin D levels; healed osteomalacia, and accelerated healing of active fractures and pseudofractures; and significantly reduced stiffness (as measured by the Western Ontario and the McMaster Universities Osteoarthitis Index (WOMAC) stiffness subscale). However, reductions in WOMAC physical function subscale and Brief Pain Inventory did not achieve statistical significance when compared to placebo. Notably, all studies to date in adults with XLH took place in moderately to severely affected patients, making extrapolation to real world patients who may present with a milder phenotype difficult [63, 72]. The reported adverse events were similar to that observed in the pediatric trials (that is, injection site reactions, headache and pain in the extremities).

Based on these studies, the European Medicines Agency (EMA) approved burosumab in the European Union for the treatment of XLH with radiographic evidence of bone disease in children $\geq$1 year and in adolescents with a growing skeleton. The FDA granted approval of burosumab to treat adults and children $\geq$1 year with XLH. Recently, EMA approved burosumab for children $\geq$1 year and adults with XLH as well. However, several open issues need to be addressed. First, in all trials performed to date, the dose of burosumab was adjusted to achieve serum phosphorus level at the low end of the normal range. The optimal therapeutic strategy, including dosing frequency and target phosphate levels, may differ in patients who have achieved a satisfactory phenotypic improvement. Second, in view of the high cost of burosumab and lack of long-term efficacy and safety data, there is a need to better define patients who will benefit the most. Because the pediatric trials were restricted to patients aged between 1 and 12 years of age, the efficacy and safety of burosumab in infants and during the pubertal spurt needs to be further evaluated. The short-term improvement of growth was modest in children treated with burosumab, and it is unknown whether treated children will experience sustained catch-up growth and achieve normal adult height. Finally, the impact of burosumab on other severe complications of XHL, such as dental abscesses and sensorineural hearing loss, needs to be addressed in future studies [18, 72].

Thus, conclusive recommendations on the use of burosumab are premature. However, given the severity of the disease in some patients and the encouraging results that have prompted the EMA and FDA to grant authorization, preliminary recommendations were recently established by an European expert panel which are outlined below.

Burosumab in Children with XLH

If available, burosumab treatment should be considered in children with XLH $\geq$ 1 year and in adolescents with growing skeletons in the following situations: radiographic evidence of overt bone disease; disease that is refractory to conventional therapy; complications related to conventional therapy; or patient's inability to adhere to conventional therapy, presumed that adequate monitoring is feasible [18]. Burosumab should be started at doses of 0.4 mg/kg body weight or 0.8 mg/kg body weight, given every 2 weeks subcutaneously. Burosumab should be titrated in 0.4 mg/kg increments to raise fasting serum phosphate levels within the lower end of the normal reference range for age, to a maximum dosage of 2.0 mg/kg body weight (maximum dose 90 mg). The half-life of burosumab is approximately 19 days, and the peak serum concentration of burosumab occurs at 7–11 days after injection. Therefore, it is was suggested to monitor fasting serum phosphate levels during the titration period between injections, ideally 7–11 days after the last injection in order to detect hyperphosphatemia [18]. After achievement of a steady state, which can be assumed after 3 months of a stable dosage, fasting serum phosphate levels should be preferably assessed directly before injections in order to detect hypophosphatemia. In some patients, burosumab might initially improve TmP/GFR while serum level of phosphate is still below the normal range owing to the high demand for phosphate of the bone. Therefore, it was recommended analyzing TmP/GFR together with fasting serum phosphate levels as a measure of drug efficacy. Although no overt hypervitaminosis D was observed during clinical trials, serum levels of 1,25(OH)$_2$ vitamin

D usually increase under burosumab therapy. Therefore, measuring these levels every 6 months and analyzing them together with the urinary calcium excretion as safety parameters are recommended. Burosumab should be withdrawn if fasting serum phosphate level is above the upper range of normal. Burosumab can be restarted at approximately half of the previous dose when serum phosphate concentration is back within the normal range. Important to note, burosumab must not be given in conjunction with conventional treatment, when fasting phosphate levels are within the age-related normal reference range before initiation of treatment, or in the presence of severe kidney impairment.

Burosumab in Adults with XLH

If available, burosumab treatment should be considered in adults with XLH with the following features: persistent bone and/or joint pain owing to XLH and/or osteomalcia that limits daily activities; pseudofractures or osteomalacia-related fractures; or insufficient response or refractory to conventional therapy [18, 63]. It is also recommended to consider burosumab treatment if patients experience complications related to conventional therapy.

The starting dose of burosumab is 1.0 mg/kg body weight (maximum dose of 90 mg) given every 4 weeks subcutaneously. Fasting serum phosphate levels should be evaluated between injections, ideally 7–11 days after the last injection [18]. After achievement of a steady state, which can be assumed after 3 months of a stable dosage, serum levels of phosphate should be assessed during the last week before the next injection. The dose should be held if fasting serum phosphate level is above the upper limit of normal. Burosumab can be restarted at approximately half of the previous dose when serum phosphate concentration is back within the normal range. Burosumab must not be given together with conventional treatment, in patients with phosphate levels within the age-related normal reference range before initiation of treatment, or in the presence of severe renal impairment.

Adjunctive Therapies

Growth Hormone

Adult heights are reduced in up to 60% of XLH patients, and short-term burosumab treatment did not substantially improve longitudinal growth in pediatric XLH patients in clinical trials as summarized in Haffner et al. [18, 73]. Although an impairment of the growth hormone (GH) insulin-like growth factor-1 axis is not the primary cause of short stature in XLH patients, the physiological antiphosphaturic effect of GH by stimulation of both renal phosphate reabsorption and 1,25 $(OH)_2D$ synthesis is a useful adjunct to conventional treatment in improving growth in poorly growing XLH patients. Several mostly uncontrolled studies and a placebo-controlled randomized trial have documented sustained increases in standardized height during treatment periods of up to 3 years. In general, prepubertal patients responded better to GH than pubertal patients [73]. Zivicnjak et al. reported on a European multicenter randomized trial on 3-year GH treatment in severely short (< -2.5 SD score (SDS)) prepubertal XLH patients [74]. Standardized height was increased in the GH group by 1.1 SDS with no change in body disproportion, whereas no significant change in standardized height was noted in controls. In line with previous uncontrolled studies, a transient rise in TmP/GFR, and consequently of serum phosphate concentrations, was noted during the first 6 months of GH treatment but not in controls. However, long-term follow-up of the same study failed to show significant benefits on the adult height most likely due to the low number of patients being followed-up until adult height, whereas in another study mean final height was significantly higher when compared to nonrandomized controls [75, 76]. Therefore, administration of GH should be considered in XLH patients with persistent short stature despite adequate metabolic control [18]. However, the efficacy of GH treatment in patients concomitant to burosumab therapy is currently unknown.

Calcimimetics

The calcimimetic agent cinacalcet was shown to reduce PTH levels in XLH patients, resulting in increases in TmP/GFR and serum phosphate [77, 78]. The cinacalcet-induced decrease in serum PTH was accompanied by a slight decrease in serum-ionized calcium concentrations and was not associated with clinical symptoms. Similarly, Geller et al. proved the efficacy of cinacalcet in increasing serum phosphate levels in patients with TIO [79]. It was suggested that long-term adjunctive treatment of XLH patients with cinacalcet may allow for lower doses of phosphate and calcitriol and thus may minimize the risk of secondary hyperparathyroidism, hypercalcemia, hypercalciuria, and nephrocalcinosis caused by high-dose phosphate and calcitriol treatment [18]. Treatment with the calcimimetics R568 alone did not improve serum phosphate levels nor the mineralization defect in *Hyp* mice, a murine animal model of XLH supporting the concept that calcimimetics should be given together with conventional treatment [80]. However, studies on the long-term efficacy and safety of this drug in XLH patients are lacking.

Surgical Care and Dental Care

As stated above, treatment aims at improving bone and teeth mineralization.

At the end of growth, the objective is to reach a neutral axis of lower limbs with knee and ankle horizontal joints. When corrective surgery is required, the bone deformities are modified through one or multiple osteotomies associated with internal or external osteosynthesis. The risk of recurrence is high, especially when the patient is young at first surgery, even in expert hands likely due to the pathophysiology of the disorder [62].

Hemiepiphysiodesis is an alternative procedure which may correct bone deformity in young patients that is proposed as guidance for growth. Caution is needed in XLH as midterm and long-term evaluations have not been produced [18].

The occurrence of endodontic infections is dramatically reduced by the early implementation of XLH treatment with vitamin D analogs and phosphate supplements restoring oral health of supplemented children similar to that of age-matched controls [20]. Both decidual and permanent teeth can benefit from the supplementation. Treatment of endodontic infections depends on the extent of the infection, the recurrence of abscesses and the expected timing of exfoliation of the tooth. Systemic antibiotics are used in the case of an acute abscess.

The prevention of endodontic infections is actually one of the goals of conventional pharmacological management of XLH. In addition to an appropriate care of XLH, prevention is supported by local prophylactic treatments such as sealing the pits and fissures of the surface of the tooth. Early and regular dental controls are recommended to ensure an optimal dentin mineralization and formation [18, 27, 81].

Expected Outcomes

Children with XLH have normal length at birth. Growth retardation, hypophosphatemia, and rickets occur during the first year of life [82, 83]. With conventional treatment, growth and skeletal deformities generally improve. Height velocity commonly increases during the first year of treatment. Leg deformities may correct during conventional treatment obviating the need for surgery, although this is not always the case. Despite general growth improvement during treatment, correction is limited and adult height is often compromised. Median adult height in XLH patients on conventional treatment (median age at start 2.3 years) reported during the last two decades amounted to -2.3 SDS (range -2.7 to -1.2 SDS) [84, 85]. Growth outcome is significantly better if treatment is initiated early (< 1 year). In three studies, the mean standardized height after treatment periods of approx. 10 years was substantially higher in XLH patients with early compared to late treatment (-0.7 SDS versus -2.0 SDS, $p < 0.01$; -1.3 SDS versus -2.0 SDS, $p = 0.06$; Fig. 9; and -0.7 SDS versus -2.0 SDS, $p < 0.01$) [85–87]. However, even early treatment does hardly normalize skeletal development, and the main effect of early treatment was the prevention of a severe height deficit during early childhood.

Zivicnjak et al. reported on age-related stature and linear body dimensions in 76 children with XLH [88]. Despite conventional treatment, they

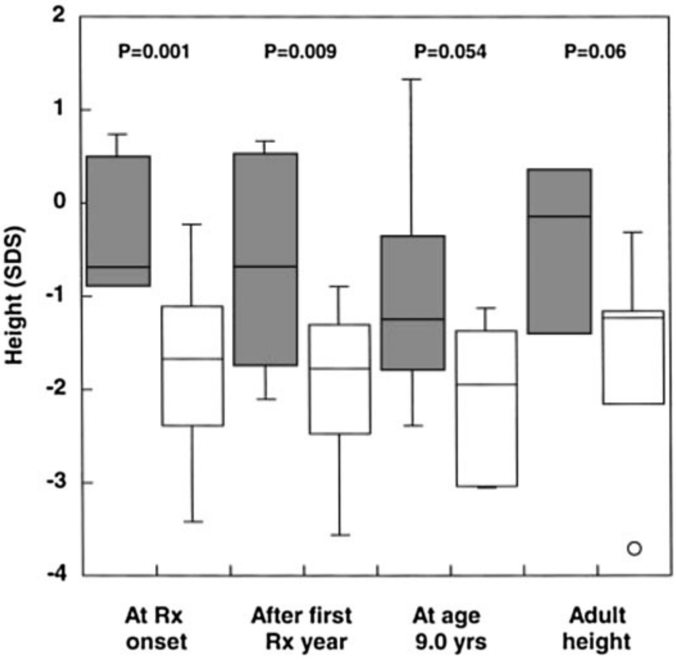

Fig. 9 Height z-scores in XLH patients started on calcitriol and phosphate treatment within the first 12 months of life 1 (■) and after the age of 12 months (□) at treatment onset, at the end of the first treatment year, at age 9 years, and at final height (adult height or predicted adult height). The bottom of each box indicates the 25th, the cross line the 50th, and the top the 75th percentile; the bottom and top lines indicate the minimum and maximum values. P values refer to the difference between groups. Rx, Treatment (Used with permission of Makitie et al. [86]

showed progressive growth failure and body disproportion during childhood, which was mainly due to diminished leg growth, whereas growth of the trunk was less affected (Fig. 10). Consequently, the sitting height index (i.e., ratio between sitting height to stature) increased with increasing age. Thus, despite medical treatment, XLH patients show uncoupled growth of legs and trunk during childhood, which in turn aggravates the preexistent disproportion between trunk and leg length. Important to note, the degree of leg bowing was only weakly associated with leg length, explaining approximately 15% of the overall variability. The finding that the lower limbs are more severely affected than the upper limbs and spine in XLH most likely reflects the fact that legs, as weight-bearing extremities, are usually exposed to higher mechanical stress loads than the upper limbs and the spine. Furthermore, growth plate activity, which in turn determines the rate of endochondral bone formation and thus bone length, is usually highest around the knees. Thus, this region is also highly prone to the development of rickets and growth impairment.

A recent North American cross-sectional study in 232 adult XLH patients all being treated with conventional therapy during childhood and adolescence revealed a high prevalence of short stature (80%), bone or joint pain/stiffness (97%), and history of pseudofractures (44%) [89]. In addition, osteophytes, enthesopathy, and spinal stenosis were reported in 46%, 27%, and 19% of patients, respectively. Similar results were reported in several European studies [90–92]. Reduced quality of life was shown in 84% of adult patients and associated with age and presence of structural lesions such as enthesopathy [90].

Treatment with burosumab results in substantial improvement of ricketic bone lesions and degree of leg deformities and nonsignificant changes in standardized height in children aged 1–12 years treated for periods of up to 16 months (vide supra). The latter may be due to rather short observation periods and/or a primary osteoblast defect in XLH. Long-term outcome data in children on burosumab treatment with respect to linear growth, dental health, and rare complications such as hearing loss are currently lacking, and multinational patient registries have been initiated to address these issues.

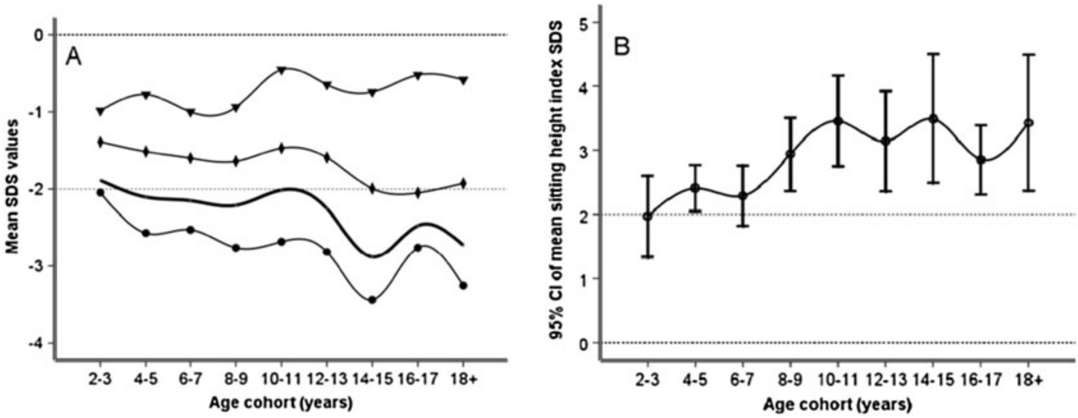

Fig. 10 Stature, sitting height, and arm and leg length (**a**) as well as the sitting height index (**b**) as a function of age in 76 children with XLH on conventional treatment. To assess age-related changes in body dimensions, all measurements were grouped according to age at the time of examination. Each age cohort comprised 8 up to 26 children with 16 up to 38 measurements. A spline function was used to fit age-related changes. Unmarked solid line stature, solid line with filled circles leg length, solid line with filled rhombuses arm length, and solid line with filled inverted triangles sitting height. The 95% CI is indicated for sitting height index [88]

Treatment of Other Forms of Hypophosphatemic Rickets

The management of patients with hypophosphatemia due to primary renal disease, i.e., tubulopathy, should be extremely cautious. Hypophosphatemia should be supplemented by multiple daily phosphate supplements using doses similar to that of XLH; large doses of cholecalciferol should be avoided, to prevent the increased production of calcitriol; in addition, 25OHD, PTH, and urinary excretion of calcium should be monitored regularly. A close follow-up of vitamin D levels – to be maintained at the lower range of normal – and of renal function is recommended in these patients [24].

Abstract

Bartter and Gitelman syndromes are rare, recessively inherited tubular disorders which are associated with hypokalemia and hypochloremic metabolic alkalosis due to stimulation of the renin-angiotensin-aldosterone system by a primary defect in salt (NaCl) handling in the thick ascending limb and distal convoluted tubule, respectively. These disorders differ in terms of age of onset, severity, presence of urinary concentrating defect and/or hypomagnesemia, and magnitude of urinary calcium excretion, reflecting the tubular segment of origin. Type 1 pseudohypoaldosteronism (PHA1) is a rare form of mineralocorticoid resistance characterized by neonatal kidney salt wasting, failure to thrive, and dehydration. The disease can be dominantly inherited, restricted to the kidney, or recessive, where mineralocorticoid resistance is affecting multiple organs.

Bartter Syndromes

Introduction

In 1962, F. Bartter and coworkers described two African American individuals presenting a novel association of kidney salt wasting, hyperaldosteronism secondary to volume contraction, hypokalemic metabolic alkalosis, hypertrophy, and hyperplasia of the juxtaglomerular apparatus, with normal/low blood pressure (BP) [1]. These subjects also exhibited polyuria, polydipsia, muscle weakness, and growth retardation. The disorder also featured increased urinary excretion of prostaglandins, high plasma renin activity, and a resistance to the pressor effects of exogenous angiotensin II [1]. For decades, many similar cases and several phenotypic variants have been progressively identified and included in a group of hypokalemic salt-losing tubulopathies, referred to as “Bartter-like syndromes” [2]. These rare tubular disorders, which are recessively inherited, are associated with hypokalemia and hypochloremic metabolic alkalosis due to stimulation of the renin-angiotensin-aldosterone system (RAAS). However, they differ in terms of age of onset, severity, presence of urinary concentrating defect and/or hypomagnesemia, and magnitude of urinary Ca^{2+} excretion. Over the years, it became apparent that these tubulopathies primarily affect salt (NaCl) handling in distinct nephron segments, based on the similarities between clinical features and the effects of loop and thiazide diuretics on the thick ascending limb (TAL) and the distal convoluted tubule (DCT), respectively.

In the adult, differentiated nephron, the TAL reabsorbs ~25% of the filtered NaCl load. The apical electroneutral cotransporter NKCC2 mediates the uptake of Na^+, K^+, and Cl^- from the lumen into the tubular cells, driven by the electrochemical gradient established by the basolateral Na^+-K^+-ATPase. The K^+ channel ROMK recycles K^+ across the apical membrane, generating a lumen-positive voltage that facilitates the paracellular reabsorption of cations including Ca^{2+} and Mg^{2+}. Basolateral ClC-Ka and ClC-Kb Cl^- channels coupled to their regulatory beta-subunit barttin are responsible for the exit of Cl^- (Fig. 1). These transport processes are crucial for the reabsorption of NaCl in the TAL and thus the urinary concentrating ability [3]. The importance of NKCC2 in the TAL is evidenced by the effects of loop diuretics which, by blocking NKCC2, induce a strong increase in urinary water, salt, and Ca^{2+} excretion.

The DCT is responsible for the reabsorption of ~5–10% of the filtered load of NaCl [4]. Driven by

Fig. 1 Molecular basis of Bartter syndromes and Bartter-like phenotypes. Approximately 25% of the filtered NaCl is reabsorbed in the thick ascending limb (TAL) via the apical Na^{+}-K^{+}-2Cl^{-} cotransporter NKCC2 (inhibited by loop diuretics), organized in parallel with the apical K^{+} channel ROMK to ensure K^{+} recycling and the lumen-positive voltage. The Na^{+}-K^{+}-ATPase and the Cl^{-} channels ClC-Ka and ClC-Kb associated with the regulatory β-subunit Barttin mediate the exit of Na^{+} and Cl^{-} ions from the cells. The thiazide-sensitive Na^{+}-Cl^{-} cotransporter NCC mediates 5–10% of the NaCl reabsorption in the distal convoluted tubule (DCT). Loss-of-function mutations in *SLC12A1* (coding for NKCC2) and *KCNJ1* (coding for ROMK) cause antenatal Bartter syndrome (aBS), whereas inactivating mutations of *BSND* encoding the beta-subunit barttin cause antenatal Bartter syndrome with sensorineural deafness (aBS with SND) and mutations in *CLCNKB* (ClC-Kb) cause classic Bartter syndrome (cBS). Inactivacting mutations of MAGED2 gene encoding MAGE-D2 cause transient antenatal Bartter syndrome (coding for NCC) are associated with Gitelman syndrome (GS). A few patients with autosomal dominant hypocalcemia due to severe gain-of-function mutations of the calcium-sensing receptor (CASR) may present a salt-losing, Bartter-like tubulopathy

the basolateral Na^{+}-K^{+}-ATPase, Na^{+} enters the DCT cells via the thiazide-sensitive Na^{+}-Cl^{-} cotransporter, NCC (or TSC, for thiazide-sensitive cotransporter). Because it is coupled to Na^{+}, Cl^{-} moves into the cell against its electrochemical gradient and then exits through the basolateral ClC-Kb channel. The DCT cells also secrete K^{+} via the ROMK channel and a K^{+}-Cl^{-} cotransporter located in the apical membrane and mediate the transcellular reabsorption of Ca^{2+} and Mg^{2+}, via the TRPV5/6 and TRPM6 channels, respectively, which belong to the transient receptor potential (TRP) channel family [5]. Thiazide diuretics, which inhibit NCC, induce a milder diuretic response than loop diuretics, typically associated with Mg^{2+} wasting and hypocalciuria.

The Bartter-like syndromes were initially classified into two major groups based primarily on age of presentation: the *antenatal Bartter syndrome* (aBS) (also named hyperprostaglandin-E syndrome (HPS), which can be transient or associated or not with sensorineural deafness (SND), and the *classic Bartter and Gitelman syndromes* (cBS and GS, respectively). The syndromes can also be classified based on their mechanism, albeit with some overlapping features. The aBS group includes disorders affecting the TAL, with furosemide-like manifestations, whereas the second group – and GS in particular – is due to a defect in the DCT, with thiazide-like manifestations [2]. From 1996, seminal studies by Lifton and colleagues identified loss-of-function mutations in transporters and channels responsible for these inherited tubulopathies. The aBS group was associated with inactivating mutations in the genes coding for NKCC2 [6] and ROMK [7], whereas inactivating mutations in barttin were detected in aBS with SND [8]. More recently, loss-of-function mutations in the melanoma-associated antigen-D2 (*MAGED2*), expressed in the TAL and DCT, were associated with a transient aBS (tBS) that spontaneously resolves during the first few months of postnatal life [9, 10]. On the other hand, inactivating mutations of ClC-Kb, also located both in the TAL and DCT, are associated with cBS [11], whereas GS is associated with mutations of NCC in the DCT [12] (Fig. 1).

A classification of these salt-losing tubulopathies, based on the clinical, physiological, and molecular insights discussed above, provides a basis to understand the phenotypes of these disorders (Table 1). When discussing such patients, the clinical diagnosis, based on relatively simple clinical criteria, should be complemented whenever possible by the genotyping information since there is only weak genotype-phenotype correlation in these disorders [13, 14].

Antenatal Bartter Syndrome

Genetics

Antenatal Bartter syndrome (aBS, MIM #601678, #241200) is a rare, life-threatening disorder characterized by massive polyuria that manifests in

Table 1 Inherited salt-losing tubulopathies

Disorder	OMIM	Inheritance	Gene locus	Gene	Protein	Affected tubular segment
Antenatal Bartter syndrome (aBS), hyperprostaglandin-E syndrome (HPS), type I Bartter syndrome[a]	#601678	AR	15q15-q21.1	*SLC12A1*	Na^+–K^+–$2Cl^-$ cotransporter NKCC2	TAL

TAL, thick ascending limb; *CCD*, cortical collecting duct; *DCT*, distal convoluted tubule; *AR*, autosomal recessive, *XLR* X-linked recessive

[a] This classification is based on the chronological order of gene discovery

[b] A digenic disorder with inactivating mutations of *CLCNKA* and *CLCNKB* has been associated with the aBS with SND phenotype

utero by polyhydramnios and premature delivery in almost all cases. Affected neonates develop salt wasting, hypokalemic metabolic alkalosis, and profound polyuria [15–17]. The disorder is accompanied by markedly elevated urinary prostaglandin E2 (PGE_2) excretion: treatment with PG synthesis inhibitors effectively reduces clinical and biochemical manifestations. The latter features explain why aBS has also been designed as hyperprostaglandin-E syndrome (HPS) [18]. As patients with aBS/HPS fail to respond to loop diuretics, a defective NaCl reabsorption in the TAL was suspected [19]. By combining a candidate gene approach with linkage analysis, Simon et al. demonstrated that aBS/HPS is due to mutations either in NKCC2 (type I BS) or in ROMK (type II BS) [6, 7] (Fig. 1). The two forms of aBS are clinically and biochemically almost indistinguishable [20].

Type I BS is due to mutations in the *SLC12A1* gene located on 15q15-q21.1 and containing 26 exons [6, 17, 21]. The *SLC12A1* gene codes for the bumetanide-sensitive NKCC2, a 121 kD protein with 12 putative membrane-spanning domains. NKCC2 is expressed in the apical membrane of epithelial cells lining the TAL and in the macula densa [22]. Loop diuretics bind to portions of transmembrane domains 11 and 12, whereas portions of domains 2, 4, and 7 are involved in ion transport [23]. Dozens of mutations in *SLC12A1* have been reported, essentially missense or frameshift [24]. Aberrant exon skipping was recently reported as a previously unrecognized mechanism by which an exonic variant in *SLC12A1* can lead to BS type I [25]. The five initial kindreds [6] and others reported subsequently [17, 21] were consanguineous, but compound heterozygotes and patients harboring only one heterozygous mutation have been reported [17, 21, 24, 26]. Although a founder mutant allele (W625X) was reported in a cohort of Costa Rican patients [26], the aBS mutations are evenly distributed throughout the *SLC12A1* gene [24]. Of note, alternative splicing of the NKCC2 pre-mRNA results in the formation of three full-length isoforms of NKCC2, which differ in their variable exon 4, their localization along the TAL, and their transport characteristics [27]. Mutations affecting the low-capacity/high-affinity isoform could thus result in a milder phenotype [17]. Novel mutations in *SLC12A1* have recently been identified by whole exome sequencing in patients with atypical type I BS presenting with varying degrees of hypercalcemia and primary hyperparathyroidism [28–30].

Type II BS is due to mutations in the *KCNJ1* gene that is located on chromosome 11q24 and contains five exons [7]. The *KCNJ1* gene encodes ROMK (also known as Kir1.1), a luminal ATP-sensitive, inwardly rectifying K^+ channel that is critical for K^+ recycling in the TAL and constitutive K^+ secretion in the distal nephron [31]. ROMK channels are assembled from four subunits, each consisting of two transmembrane domains flanking a conserved loop that contributes to the pore and selectivity filter and cytoplasmic N^- and C^- termini that contain regulatory and oligomerization domains [32]. ROMK exists in three N-terminal splice variations that all behave as rectifying K^+ channels gated by intracellular pH [31]. Through the recycling of reabsorbed K^+ back to the lumen, ROMK is believed to be a regulator of NKCC2 cotransporter activity. Therefore, loss of function in ROMK, as well as in NKCC2, disrupts NaCl reabsorption in the TAL. Mutations in *KCNJ1* that cosegregate with aBS include missense, nonsense, frameshift, and deletions [7], [20, 33–37]. The first mutations were reported in exon 5, common to all ROMK isoforms [7, 20], but homozygous deletions in exons 1 and 2 have also been reported [33, 36].

Clinical Manifestations

Typical features of aBS type I (NKCC2) and type II (ROMK) include polyhydramnios (within the second trimester of gestation); premature delivery (usually around 32 weeks); severe polyuria; life-threatening episodes of dehydration; hypercalciuria, leading to nephrocalcinosis within the first months of life; and activation of the RAAS (Table 2). The polyuria can be massive (>20 mL/kg/h) despite adequate fluid replacement. Magnesium wasting is not common in aBS [38], although hypomagnesemia was evident in half of the Costa Rican patients [39]. Failure to thrive and growth retardation are invariably observed [16, 39, 40]. A peculiar facies, characterized by a

Table 2 Clinical and biochemical features of Bartter syndrome (BS) and Gitelman syndrome (GS)

Feature	Type I BS	Type II BS	Type IV BS	Type III BS	Type V BS	GS (*SLC12A3*)

Urinary PGE2 excretion	High	High	High	High		Normal

[a] SND is present in case of digenic disorder with inactivating mutations of *CLCNKA* and *CLCNKB*

triangularly shaped face, prominent forehead, large eyes, protruding ears, and drooping mouth, has been reported but could reflect dystrophic premature babies [27, 39]. Systemic manifestations including fever of unknown origin, diarrhea, vomiting, and generalized convulsions, which have been attributed to enhanced systemic overproduction of PGE, and recurrent urinary tract infection may occur [38, 41]. Osteopenia is common in aBS [16, 42], associated with high urinary excretion of bone resorption markers [43]. Increased urinary PGE2 excretion is usually detected, although not invariably [2, 16]. Hypophosphatemia with decreased tubular phosphate reabsorption has been described, possibly related to tubular damage and hypokalemic nephropathy [40, 43]. High Cl^- and aldosterone concentrations in the amniotic fluid have been reported [16].

Some phenotype variability among NKCC2-deficient patients has been reported, including absence of hypokalemia and/or metabolic alkalosis during the first years of life and persistent metabolic acidosis or hypernatremia [21]. The Costa Rican cohort harboring the W625X founder allele showed a somewhat milder phenotype with a median age of diagnosis at 10 months of life and no necessity of indomethacin treatment in most patients [26, 39]. A late-onset presentation (age

13 and 15 years) with mild polyuria and borderline hypercalciuria has been reported in two compound heterozygote brothers for NKCC2 mutations [44].

While kidney function is generally well preserved in aBS [21, 39], chronic kidney disease (CKD) leading to ESRD has been reported [39, 45, 46]. The potential mechanisms that could lead to kidney damage in aBS include consequences of early neonatal events and dehydration episodes, hypokalemic nephropathy, nephrocalcinosis, and potential nephrotoxicity of nonsteroidal anti-inflammatory drugs (NSAID) [45, 47, 48]. Kidney biopsies of children with aBS revealed a marked hypertrophy and hyperplasia of the juxtaglomerular apparatus, with stimulation of the renin-angiotensin system [49, 50]. This feature is not specific for aBS and may be observed in all Bartter-like syndromes. Reinalter et al. [48] showed inflammatory infiltrates, with areas of interstitial fibrosis, focal tubular atrophy with thickening of basement membranes and degenerated tubular epithelia, and focal segmental mesangial matrix increase and hypercellularity in kidney biopsies obtained in 10aBS/HPS patients. Of interest, patients harboring ROMK mutations had only minimal histological lesions as compared with NKCC2-deficient patients and cBS patients [48].

Because NKCC2 and ROMK are functionally coupled in the apical membrane of the TAL, patients with defective ROMK have a very similar clinical picture to NKCC2 deficiency, with polyhydramnios, premature delivery, severe neonatal polyuria with isosthenuria, and hypercalciuria with secondary nephrocalcinosis [2, 38]. However, there is an important difference in that ROMK-deficient patients show a transient hyperkalemia during the first days of life, correlated with gestational age [38, 51]. The association of early hyperkalemia with hyponatremia and hyperreninemic hyperaldosteronism may erroneously suggest the diagnosis of pseudohypoaldosteronism type 1 (PHA1) [51]. Potassium wasting in these cases may not be apparent until 3–6 weeks postnatally, leading to modest hypokalemia in most patients. Typically, hypokalemia in ROMK-deficient patients is less severe than that observed in NKCC2 patients [36, 38].

By exome sequencing approximately 3000 subjects in the Framingham Heart Study (FHS) cohort, Ji et al. showed that heterozygote carriers of inactivating mutations in NKCC2 and ROMK (as well as NCC) had significantly lower systolic and diastolic BP and a significant reduction in the risk of developing hypertension [52]. It was subsequently demonstrated that polymorphisms in *KCNJ1* were associated with BP values in a cohort of 2037 adults after adjusting for age, sex, and familial correlations [53]. Since the vast majority of these rare variants in NKCC2 and ROMK have a loss-of-function effect, it can be concluded that such rare variants may exert a profound influence on BP regulation [54, 55].

Differential Diagnosis

Antenatal BS should always be suspected in the face of polyhydramnios due to fetal polyuria. Patients with type II aBS due to ROMK deficiency may show a transient hyperkalemia, which can mimic PHA1. However, PHA1 is characterized by permanent hyperkalemia with metabolic acidosis, whereas type II aBS patients typically have metabolic alkalosis, as well as hypercalciuria and nephrocalcinosis. In some patients with aBS, the urinary concentrating defect is so severe that it can lead to hypernatremia, resembling nephrogenic diabetes insipidus [21]. Some patients with aBS may lack metabolic alkalosis during the first year of life or even present a transient metabolic acidosis with defective urinary acidification [56]. This association, which probably results from medullary nephrocalcinosis, can mimic incomplete distal renal tubular acidosis [21]. Other causes of pseudo-Bartter syndromes will be discussed in the section "Classic Bartter Syndrome."

Pathophysiology

Functional investigations of pathogenic NKCC2 mutations in *Xenopus laevis* oocytes revealed a low expression of normally routed but functionally impaired transporters [57]. Reduced transport function, reduced Na^+ affinity, and defective processing were also observed when expressing rare NKCC2 variants associated with low BP in the FHS [58, 59]. A partial intrinsic transport defect was demonstrated in the F177Y mutant, which may account for the attenuated phenotype of the affected patients [44]. Similar studies provided insights into the role of ROMK in aBS. Two C-terminal mutations located nearby or inside the putative protein kinase A (PKA) phosphorylation site of ROMK showed a decreased open probability of the channel [60]. Missense mutations located in the intracellular N- and C-termini were shown to encode functional channels, but with altered pH gating [35]. Starremans et al. investigated eight ROMK mutants and showed that loss of function may result from defective cellular routing to the plasma membrane or impaired channel function [37]. Peters et al. [61] identified defective membrane trafficking in 14/20 naturally occurring ROMK mutations and showed that two early inframe stop mutations could be rescued by aminoglycosides, resulting in full-length ROMK and correct trafficking to the plasma membrane. More recently, type II BS mutations in ROMK have been associated with accelerated endoplasmic reticulum (ER)-associated degradation (ERAD) [62]. Rare variants of ROMK associated with low BP in the FHS also showed reduced ROMK channel activity by different mechanisms [63].

The functional data obtained in vitro suggest that loss-of-function mutations in NKCC2 and ROMK disrupt NaCl transport in the TAL, leading to salt wasting, volume contraction, and stimulation of the RAAS. In turn, enhanced Na^+ delivery to the distal nephron and reabsorption of Na^+ via the Na^+ channel ENaC stimulate urinary excretion of K^+ and H^+, causing hypokalemic metabolic alkalosis (Fig. 2). These changes are already observed prenatally, with polyhydramnios, high Cl^- concentrations, and increased aldosterone levels in the amniotic fluid [64, 65]. Chronic volume contraction, elevated levels of angiotensin II, and intracellular Cl^- depletion stimulate PGE2 production, which further inhibits NaCl transport in the TAL and contributes to the washout of the osmotic gradient through enhanced medullary perfusion [2]. The inhibition of NKCC2 in the macula densa could impair the luminal Cl^- sensing of these cells, which may disrupt the tubuloglomerular feedback and further activate renin release from juxtaglomerular cells [66]. It also appears that cyclooxygenase-2 (COX-2) is induced in the macula densa of children with aBS [67], which could further contribute to hyperreninemia [68]. The early neonatal hyperkalemia harbored by some ROMK-deficient patients is explained by the role of ROMK in K^+ secretion in the aldosterone-sensitive distal nephron (ASDN). The transient nature of the hyperkalemia [51]

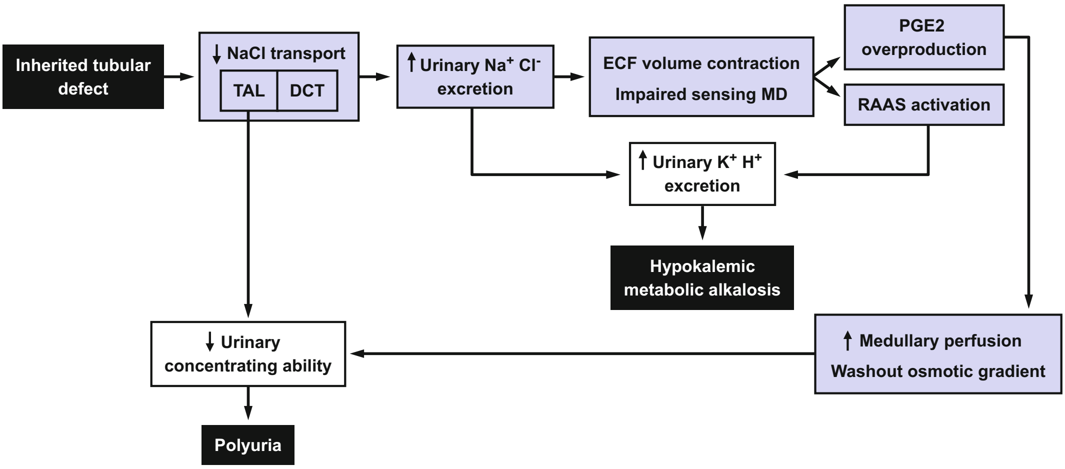

Fig. 2 Physiopathology of hypokalemic metabolic alkalosis and polyuria in Bartter syndrome. See text for details. *Abbreviations*. TAL, the thick ascending limb; DCT, distal convoluted tubule; MD, macula densa; RAAS, renin-angiotensin-aldosterone system

likely reflects the postnatal appearance and activation of other ASDN K^+ secretory channels, notably the BK channel, that can compensate for the absence of ROMK [69, 70].

The impaired Cl^- transport in the TAL affects the lumen-positive electrical potential, causing persistent hypercalciuria and early-onset nephrocalcinosis in aBS. Magnesium wasting and overt hypomagnesemia do not reliably segregate with aBS, consistent with the observation that chronic furosemide treatment is not generally associated with hypomagnesemia [71]. Possibly, the loop of Henle or more distal segments may adapt and compensate more efficiently for Mg^{2+} than Ca^{2+} in this syndrome. In the TAL, adaptation might involve tight junction proteins (claudin16/claudin19), whereas increased PGE2 synthesis may contribute to increased Mg^{2+} reabsorption in the DCT [72]. It has been suggested that bone resorption and PGE2-mediated increase in calcitriol may contribute to hypercalciuria in aBS [42, 73]. Schurman et al. [74] showed that elevated levels of angiotensin II may stimulate the release of basic fibroblast growth factor (b-FGF), with a resulting increase in bone resorption via a prostaglandin-dependent mechanism.

NKCC2 knockout (KO) mice show massive perinatal fluid wasting and dehydration, leading to kidney failure and death prior to weaning [75]. Treatment of these mice with indomethacin from day 1 allowed 10% mice to survive, despite polyuria, hydronephrosis, hypokalemia, and hypercalciuria. Similarly, the ROMK KO mice manifest early death associated with polyuria, polydipsia, and impaired urinary concentrating ability [76]. Approximately 5% of these mice survive the perinatal period but show kidney failure, hypernatremia, and metabolic acidosis. Micropuncture analysis revealed that the absorption of NaCl in the TAL was reduced, with severe impairment of the tubuloglomerular feedback. Another strain of ROMK-null mice with a BS-like phenotype showed increased survival to adulthood, due to compensatory mechanisms mostly active in the DCT [77]. Lu et al. demonstrated that the CFTR Cl^- channel may regulate the ATP sensitivity of ROMK in the TAL, which could explain why patients with cystic fibrosis are prone to develop the pseudo-Bartter features of hypokalemic metabolic alkalosis [78].

Treatment

The initial treatment of preterm infants or neonates with aBS should focus on the correction of dehydration and electrolyte disorders, which often requires continuous saline infusion in a neonatal intensive care unit. Elevated levels of urinary PGE2 provided a rationale for NSAIDs, and indomethacin has been widely used [2, 16, 38, 40, 56]. Typically, administration of indomethacin starting 4–6 weeks after birth, when massive urinary electrolyte losses have been controlled and hypokalemic metabolic alkalosis is established, corrects both the systemic and biochemical manifestations of aBS [38]. Indomethacin (at doses ranging from 0.5 mg/kg/day to 2.5 mg/kg/day) reduces polyuria, improves hypokalemia, normalizes plasma renin levels, and reduces hypercalciuria [16, 38, 40, 41, 56]. However, the potential benefit of indomethacin administration in premature babies and neonates should be weighed against potential risks of severe gastrointestinal complications, such as ulcers, perforation, and necrotizing enterocolitis [16, 40, 79]. In particular, administration of indomethacin in newborn infants with defective ROMK may be complicated by oliguric kidney failure and severe hyperkalemia. At any time, the ROMK-deficient patients are particularly sensitive to indomethacin, with doses well below 1 mg/kg/day sufficient to maintain normal plasma K^+ levels [80]. Similarly, the potential benefit of prenatal treatment with indomethacin [80] should be weighed against the lack of evidence for hyperprostaglandinism in the fetus [16] and the negative effects of NSAID on the ductus arteriosus and the development of the kidney [79]. Selective and nonselective cyclooxygenase inhibitors can also be used for treatment [80]. As an alternative to indomethacin, the COX-2 selective inhibitor rofecoxib ameliorated clinical and biological manifestations in aBS patients, with significant suppression of PGE2 and correction of hyperreninemia [68, 81]. However, a case of reversible acute renal failure associated with rofecoxib in an 18-month-old girl with aBS has been reported [82].

Importantly, it should be remembered that HPS is secondary to volume depletion [16] and that the appropriate compensation for fluid and salt wasting remains the essential priority. Additional K^+ supplementation is required, more often for NKCC2-deficient than ROMK-deficient patients [2, 38]. In some cases, a K^+-sparing diuretic (e.g., spironolactone) is necessary to increase serum K^+ levels [1, 16]. Treatment with angiotensin-converting enzyme (ACE) inhibitors has been reported effective in a few cases [40, 83] but should be used with caution as these drugs could block the distal compensatory Na^+ reabsorption. Thiazides should not be used to reduce hypercalciuria, since they interfere with compensatory mechanisms in the DCT and further aggravate dehydration.

The appropriate management of aBS with correction of fluid and electrolyte disorders, indomethacin, and K^+ supplements results in catch-up growth and normal pubertal and intellectual development [16, 40]. However, most patients show a persistent deficiency in height and weight [39, 48]. Correction of hypercalciuria is usually partial, with progression of nephrocalcinosis and development of CKD in some cases [16, 40, 45, 56]. Chaudhuri et al. [46] reported a case of severe aBS in whom pre-emptive nephrectomy followed by a living-related donor kidney transplantation resulted in correction of metabolic abnormalities and excellent graft function.

Few long-term follow-up studies of patients with BS have been published. A long-term follow-up study of 15 children with homozygous or compound heterozygous mutations in *SLC12A1* or *KCNJ1* by Puricelli et al. [84] revealed that in response to potassium chloride supplementation and indomethacin treatment, patients presented a satisfactory somatic growth after a median follow-up of more than 10 years. An estimated glomerular filtration rate (eGFR) of <90 ml/min/1.73 m^2, occasionally associated with overt proteinuria, was present at follow-up in 25% of the patients, which can be possibly explained by nephrocalcinosis and/or prolonged hypokalemia or by the side effect of the NSAIDs. Of note, 3/15 patients developed gallstones which might represent a new complication of aBS [84]. In another long-term follow-up study (median 8.9 years, between 1984 and 2014) of 45 children with pathogenic variants in *SLC12A1* ($n = 8$), *KCNJ1* ($n = 8$), *CLCNKB* ($n = 17$), *BSND* ($n = 2$), and *SLC12A3* ($n = 10$), impairments at the last follow-up were found in growth, albeit within the normal range (median height standard deviation score -1.2) and eGFR <90 mL/min/1.73 m^2, predominantly with *SLC12A1* and *KCNJ1* mutations [85]. Pathological albuminuria was detected in 31 of the 45 children. These observations underscore the critical need that children diagnosed with BS are closely monitored for glomerular and tubular function.

Transient Antenatal Bartter Syndrome (tBS)

Genetics

In 2013, Laghmani et al. [9] described a very severe but transient BS characterized by the very early onset of extreme polyhydramnios, prematurity, and perinatal mortality. Whole exome sequencing of an affected male infant and his mother in the index family, in which the male offspring of three pregnancies presented with this severe phenotype, identified a truncating mutation in the *MAGED2* gene [9]. *MAGED2* maps to the X chromosome and encodes the melanoma-associated antigen D2 (MAGE-D2) protein [86]. Sequencing of additional families with affected male infants with similar clinical presentations and women with recurrent idiopathic polyhydramnios during pregnancies with male fetuses confirmed the presence of at least 15 *MAGED2* mutations that cosegregate with disease [9, 10]. The identification of two female patients in a French cohort was proposed to reflect selective inactivation of the X chromosome [10]. Mutations in *MAGED2* associated with aBS include missense, nonsense, splicing, frameshift, and deletions [9, 10]. This subtype of aBS has been named type V transient aBS (MIM #300971) (Fig. 1).

Clinical Manifestations

Patients harboring mutations in *MAGED2* show the most severe form of aBS, with maternal polyhydramnios beginning by week 20 of gestation, necessitating serial amnioreductions and in some cases antenatal indomethacin treatment [10], and severe prematurity, with ~40% affected fetuses born at <28 weeks GA [9], [10]. Polyuria is severe and mortality is high [9], [10]. Patients with *MAGED2* mutations can be distinguished from other aBS groups by their higher birth weight percentile for GA and higher plasma Cl^- concentration [10]. They present with lower serum bicarbonate values compared to other subjects with aBS, suggesting that MAGE-D2 also affects bicarbonate transport. Unlike the other forms of BS, salt and water losses in transient aBS spontaneously resolve typically between 2 and 18 months of age [9, 10].

Pathophysiology

MAGE-D2 is expressed in the TAL and DCT of both fetal and adult kidneys [9]. Immunohistochemical analyses of the kidney of a stillborn fetus carrying a *MAGED2* mutation in the index family reported by Laghmani [9] revealed a weak apical signal for NKCC2 and NCC, with protein predominantly cytoplasmic, colocalizing to the endoplasmic reticulum (ER) [9]. These observations are consistent with the Na^+ wasting and polyuria in affected infants and suggest that MAGE-D2 participates in maturation of proteins in the ER for transport to the apical membrane.

Using a proteomic approach applied to a heterologous expression system, Laghmani et al. [9] showed that wild-type but not mutant MAGE-D2 binds to the chaperone protein Hsp40 (DNAJB1) and the G protein subunit Gs-alpha (GNAS). Hsp40 modulates protein folding and stability, especially under ER stress conditions, and regulates NCC biosynthesis in the ER [88]. Laghmani et al. [9] showed that MAGE-D2 protects NKCC2 and NCC from ER-associated degradation (ERAD), promoting total and cell surface expression and activity of the transmembrane proteins. Thus, Hsp40 has been proposed to interact with MAGE-D2 to regulate ERAD of NKCC and NCC. Activation of Gs-alpha enhances generation of cAMP as well as surface expression, phosphorylation, and activity of NKCC2 and NCC [89, 90]. These observations, in light of the finding that knockdown of *GNAS* in mice reduces NKCC2 protein abundance [91], suggest that MAGE-D2 modulates trafficking of these transporters to the cell surface. In sum, loss-of-function mutations in MAGE-D2 are predicted to inhibit NKCC2 and NCC expression and activity. The severity of this form of aBS reflects the dual effects on the major Na^+ absorptive transport pathways in the TALH and DCT.

The transient nature of the disease may reflect (i) a maturational increase in sensitivity of adenylate cyclase to vasopressin as activity of phosphodiesterase, which catalyzes the degradation of cAMP, declines [92, 93] which compensates for the low Gs-alpha activity to enhance cAMP generation, and/or (ii) higher levels of oxygenation with advancing pregnancy/delivery may reduce hypoxia-induced ERAD and thus protect Hsp40-modulated NKCC2 and NCC biogenesis, thereby reducing the need for MAGE-D2 [9, 94].

Treatment

The treatment for tBS is similar to that described above for **antenatal Bartter syndrome**, recognizing that the kidney phenotype of type V BS is transient and resolves spontaneously. A genetic diagnosis and close clinical follow-up should ensure that the patient is not subject to overtreatment with NSAIDs with potential toxicity.

Antenatal Bartter Syndrome with Sensorineural Deafness

Genetics

In 1995, Landau et al. [95] described a subtype of aBS/HPS associated with sensorineural deafness (SND) in five affected subjects from an inbred Bedouin kindred. These patients had severe salt wasting and fluid loss, with poor response to indomethacin and, most often, CKD [95, 96]. By studying the original kindred, Brennan et al. mapped the disease-causing gene to chromosome 1p31 [97]. In 2001, Birkenhager et al. [8] identified a novel gene, *BSND*, within the critical interval and detected inactivating mutations in affected individuals. This subtype of aBS was named aBS with SND, or type IV BS (MIM #602522). The original mutations included a splicing mutant, a deletion of two exons, three missense mutations affecting a conserved residue close to the first putative membrane domain, and one mutation resulting in the loss of the start codon [8]. The *BSND* gene consists of four exons. It encodes barttin, a 320 amino acid protein that contains two putative transmembrane domains and serves as an essential subunit of the basolateral Cl^- channels ClC-Ka and ClC-Kb. Barttin is expressed in the thin limb and TAL and in the DCT (Fig. 1) and in the stria vascularis surrounding the cochlear duct in the inner ear [8, 98]. BS type IVa is due to mutations in *BSND*, whereas the phenotypically indistinguishable BS type IVb is caused by mutations in the genes encoding both basolateral Cl^- channels. As Cl^- efflux is necessary for depolarization of hair cells in the inner ear, loss of function of barttin and/or both Cl^- channels in BS IV (vs. BS III where ClC-Ka remains intact) is associated with deafness.

Clinical Manifestations

Typically, patients harboring mutations in *BSND* show a severe form of aBS, with maternal polyhydramnios beginning at week 25 of gestation, severe prematurity, life-threatening neonatal episodes of dehydration, polyria with hypo- or isosthenuria, and increased urinary PGE2 excretion [2, 99] (Table 2). The patients are deaf and show a severe growth defect, with delayed motor development [96]. They present multiple episodes of fever, vomiting, and bacterial infections. Jeck et al. [96] reported progressive CKD in all patients, attributable to glomerular sclerosis and tubular atrophy. However, Shalev et al. reported that early kidney failure is not a uniform finding [99]. In contrast with patients harboring mutations in NKCC2 and ROMK, barttin-deficient patients exhibit only moderate and transient hypercalciuria and do not show nephrocalcinosis [2, 99]. This could be due to defective NaCl transport in both the TAL and DCT, with divergent effects on urinary calcium excretion somehow similar to a combined action of a loop diuretic with a thiazide. Accordingly, barttin-deficient patients may show a severe Mg^{2+} wasting, caused by a defect in both the paracellular (TAL) and transcellular (DCT) pathways of Mg^{2+} reabsorption [2]. Of note, a lack of diuretic response to furosemide and to hydrochlorothiazide was evidenced in one barttin-deficient patient, supporting a defect in both TAL and DCT [100].

There is some degree of phenotype variability among patients with *BSND* mutations. Miyamura et al. [101] reported a patient harboring the loss-of-function G47R mutation of *BSND* who presented at age 28, with congenital deafness but without polyhydramnios, premature labor, or severe salt wasting in the neonatal period. In contrast, five patients from two unrelated Spanish families harboring the same G47R mutation presented with polyhydramnios, premature birth, and salt loss [102]. Kitanaka et al. [103] reported a patient harboring two mutations in *BSND* (Q32X and G47R) who presented with relatively mild perinatal clinical features but developed end-stage kidney failure at age 15, requiring kidney transplantation. The functional evaluation of the G210S mutation of *BSND* revealed only a very mild disturbance in the current-voltage relationship [104], possibly accounting for a milder phenotype [99]. Riazuddin et al. identified a missense mutation (I12T) of *BSND* in four kindreds, associated with nonsyndromic deafness. Of note, the I12T mutation does not affect the Cl^- channel function and only interferes with the chaperone function of barttin in intracellular trafficking [105]. Functional studies of six *BSND* mutations have revealed that missense mutations can affect the function of ClC-K/barttin despite normal trafficking and membrane insertion of the channels or by binding less efficiently to ClC-K, whereas nonsense mutants interfere with the apical surface sorting [106].

Kidney biopsies obtained in patient with *BSND* mutation showed variable features including hyperplasia of the juxtaglomerular apparatus, mild mesangial hypercellularity, mild to severe tubulointerstitial fibrosis, areas of tubular atrophy, and sclerosed glomeruli [96, 99].

Pathophysiology

Functional expression studies revealed that barttin is an essential beta-subunit for the Cl^- channels ClC-Ka and ClC-Kb, by stimulating Cl^- currents and enhancing surface expression of these channels [98]. Barttin stimulates Cl^- flux through the human ClC-Ka by modifying the gating of these double-barreled channels [107]. ClC-Ka and ClC-Kb are two members of the ClC gene family that are located on the basolateral membrane of the cells lining the thin ascending limb (ClC-Ka only), TAL and DCT, and the intercalated cells of the collecting duct. ClC-Ka and ClC-Kb are also expressed in the inner ear, where they colocalize precisely with barttin in specialized, K^+-secreting cells of the stria vascularis and the vestibular organ [98]. The co-expression of barttin with ClC-Ka/b channels is crucial for NaCl reabsorption in the TAL/DCT (Fig. 1) and K^+ recycling in the inner ear. Disease-causing mutations in barttin disrupt the Cl^- exit from the TAL and DCT, causing the severe salt-losing tubulopathy. Furthermore, the defective barttin-ClC-Ka/b complex impairs the basolateral recycling of Cl^- in the stria vascularis, decreasing the secretion of K^+ into the endolymph and causing SND [98, 108]. The role of barttin as an essential beta-subunit for ClC-Ka and ClC-Kb has been substantiated by reports of patients showing a typical aBS with SND phenotype indistinguishable from barttin-deficient patients, but due to a digenic disease caused by loss-of-function mutations in both *CLCNKB* and *CLCNKA* genes [109, 110].

A barttin KO mouse model was previously generated, but the mice died within days after birth because of severe dehydration [111]. Nomura et al. generated a knockin mouse model carrying the disease-causing R8L mutation of *BSND* [112]. These mice presented with hypokalemia, metabolic alkalosis, and decreased distal NaCl reabsorption under a low-salt diet. Plasma membrane localization of both mutant barttin and the ClC-K channel was impaired as demonstrated by immunofluorescence and immunoelectron microscopy, and transepithelial chloride transport in the thin ascending limb of Henle's loop as well as thiazide-sensitive chloride clearance was significantly reduced. These changes were correlated with the reduced quantity of mutant barttin localized to the plasma membrane [112].

Treatment

Barttin-deficient patients are managed primarily with intravenous fluids in neonatal intensive care units. In contrast with other forms of aBS, and despite high levels of urinary PGE2, the effect of indomethacin on growth and correction of electrolyte disorders is rather poor [96, 99]. Hypokalemic metabolic alkalosis persists despite high doses of NaCl and KCl supplementation [96]. Zaffanello et al. [100] reported that combined therapy with indomethacin and captopril was needed to discontinue intravenous fluids and improve weight gain in a single patient. A preemptive nephrectomy for refractory electrolyte and fluid losses and persistent failure to thrive, followed by peritoneal dialysis and successful kidney transplantation, has been reported in a 1-year-old child with type IV BS [46]. Recently, treatment with the Hsp90 inhibitor 17-allylamino-17-demethoxygeldanamycin (17-AAG), known to rescue ER-trapped mutant proteins in vitro, increased the plasma membrane expression of mutant barttin in the kidney and inner ear and improved the electrolyte disorders and hearing loss of the R8L knockin mouse model [113].

Classic Bartter Syndrome

Genetics

Classic Bartter syndrome (cBS, or type III BS, MIM #607364) usually presents during infancy or early childhood, with a phenotype similar to the original description given by Bartter et al. [1], i.e., without the prenatal onset and the nephrocalcinosis seen in the aBS variant. The cBS variant is caused by mutations in the *CLCNKB* gene located on 1p36 ([11, 114]. The gene, which contains 19 exons, encodes the basolateral Cl^- channel ClC-Kb, which mediates Cl^- efflux from epithelial cells lining the TAL and DCT [11, 108] (Fig. 1). There is a high rate of deletions encompassing a part of or the entire *CLCNKB* gene [11, 114]. It is hypothesized that the close vicinity of the almost identical *CLCNKA* and *CLCNKB* genes, which are separated by only 11 kb, predisposes to a high rate of rearrangements, for example, by unequal crossing over as demonstrated in two kindreds

[11, 114]. In addition, missense, nonsense, small insertions/deletions, frameshift, and splice-site mutations have also been reported (http://www.hgmd.cf.ac.uk) [115, 116]. A founder mutation (A204T) affecting a highly conserved residue has been reported at the homozygous state in ten patients from nine unrelated, non-consanguineous families in Spain [117]. As expected for a recessively transmitted disorder, a significant number of subjects originate from consanguineous kindred [11, 114].

Pathophysiology

As mentioned earlier (see Pathophysiology section of "Antenatal Bartter Syndrome with Sensorineural Deafness"), ClC-Kb is a plasma membrane channel that belongs to the CLC family of chloride channels/exchangers [108]. ClC-Kb and the closely related ClC-Ka isoform are located on the basolateral membrane of the cells lining the thin ascending limb (ClC-Ka only), TAL and DCT cells, as well as in the intercalated cells of the collecting duct (Fig. 1). They both require the beta-subunit barttin to facilitate their insertion in the plasma membrane and generate Cl^- currents [98, 104]. Disease-causing missense mutations of ClC-Kb result in significant reductions or the loss of ClC-Kb/barttin currents [98, 118]. Thus, inactivating mutations in ClC-Kb affect the basolateral exit of Cl^-, which in turn reduces the reabsorption of NaCl in the TAL and DCT. The phenotypic variability of type III BS, which ranges from aBS/HPS in some cases to typical GS in others, may be explained by the wide distribution of ClC-Kb [38, 114] and the fact that alternative pathways for Cl^- exit could partially compensate for ClC-Kb inactivation in the kidney [114, 119]. The nature of *CLCNKB* mutations may also play a role [118, 120]. Functional studies of nine *CLCNK*B mutations in *Xenopus laevis* oocytes revealed three classes of mutations: one characterized by impaired or reduced surface expression due to partial or total retention in the ER, a second characterized by reduced channel insertion at the plasma membrane and altered gating, and a novel third group of functionally inactive mutants expressed normally at the plasma membrane, consistent with a channel gating impairment [121, 118]. Importantly, none of the type III BS patients with ClC-Kb mutations is deaf, because the function of ClC-Kb/barttin channels in the inner ear can be replaced by ClC-Ka/barttin. Only the disruption of the common β-subunit barttin [98] or the combined loss of ClC-Ka and ClC-Kb [109, 110] results in a Cl^--recycling defect that lowers K^+ secretion in the stria vascularis to a pathogenic level.

Mice with targeted disruption of ClC-K2, the murine ortholog of ClC-Kb, develop a phenotype characterized by salt loss, marked hypokalemia, and metabolic alkalosis [122]. These KO mice failed to respond to furosemide and exhibited a blunted natriuretic response to thiazide, consistent with the critical role of this Cl^- channel in the TAL and ASDN [122]. Mice lacking ClC-K1, the murine ortholog of ClC-Ka, show a phenotype of nephrogenic diabetes insipidus, with no modification in the fractional excretion of Na^+ and Cl^- and no hypokalemic alkalosis [123]. These features are caused by the loss of Cl^- transport across the thin ascending limb, which is essential for generating a hypertonic interstitium [123]. No corresponding human disease linked to loss-of-function mutations of *CLCNKA* has been described. It must be noted that genetic variants of *CLCNKA* have been associated with salt-sensitive hypertension [124]. More recently, a common, loss-of-function variant of *CLCNKA* was identified as a risk factor for Caucasian heart failure [125].

Clinical Manifestations

Patients harboring mutations of ClC-Kb present a broad spectrum of clinical features (Table 2) that range from the aBS/HPS phenotype, characterized by polyhydramnios, isosthenuria, and hypercalciuria, to the classic BS phenotype, with less impaired concentrating ability and normal urinary calcium excretion, to a GS-like phenotype with hypocalciuria and hypomagnesemia [2, 38, 114, 117]. Most patients have episodes of hypokalemic alkalosis and dehydration complicated with muscular hypotonia and lethargy during the first years of life. They are also characterized by increased urinary excretion of PGE2 [2, 38, 114]. The median duration of pregnancy was 38 weeks in the series of Jeck et al. [2], and failure to thrive is common [38, 117]. The diagnosis of Bartter syndrome is usually made during the first year of life, but prenatal (with history of mild maternal polyhydramnios) and late-onset cases are also reported [126]. Most patients with classic BS show failure to thrive and growth retardation [43, 127, 128]. The latter can be due to profound growth hormone deficiency [129]. Like in the antenatal variants, osteopenia with increased markers of bone resorption can be observed [43].

The electrolyte abnormalities are usually severe at presentation, with low plasma Cl^- and severe hypokalemic alkalosis [115]. Increased plasma renin levels, with high or inappropriately normal (with respect to the hypokalemia) aldosterone levels, are typically observed [38, 114]. Polyuria is not uniformly found in classic BS. Iso/-hyposthenuria was only evidenced in approximately one-third of patients, whereas some achieved urinary osmolality above 700 mOsm/kg [2]. The persistence of such a concentrating ability suggests that patients lacking ClC-Kb have a residual TAL function. This is further supported by the fact that only ~20% of patients had sustained hypercalciuria [38]. Nephrocalcinosis was reported in 4/36 affected children [114] but was not detected in three other series [117, 127, 128]. The patients may show a mild hypophosphatemia, which could be related to tubular damage and hypokalemic nephropathy [40, 43]. Isolated cases present with manifestations of renal Fanconi syndrome or distal renal tubular acidosis [117]. About half of the patients lacking ClC-Kb have hypomagnesemia [114]. Several patients harboring mutations in *CLCNKB* show overlapping features of cBS (presentation within the first year of life with episodes of dehydration) and GS (hypomagnesemia with hypocalciuria [114, 119, 130, 131]. Sun et al. [132] reported a patient with cBS who had bilateral sclerochoroidal calcification attributed to persistent hypomagnesemia for 26 years despite magnesium supplementation.

If the full phenotypic spectrum of the Bartter-like syndromes can result from mutations in *CLCNKB*, a significant clinical heterogeneity is observed among patients harboring the same mutation and even between siblings [111, 117, 133]. Mutations in barttin-binding sites of ClC-Kb, dimer interface, or selectivity filter of the channel have been proposed to result in more severe functional consequences [134]. The most common mutation, a homozygous deletion of the entire *CLCKNB*, is typically associated with significant phenotype variability [114, 119, 128, 135]. Yet the authors of a large series of 115 patients reported an association of complete loss-of-function mutations with younger age at diagnosis and CKD [13]. Ethnic differences may participate in the phenotype variability [2]. Indeed, the two original patients described by Bartter were of African American origin [1], and early reports suggested that the course of BS may be more severe in African Americans [136].

A vascular hyporeactivity to the infusion of angiotensin II was originally described by Bartter et al. [1]. This feature is not consistently observed, probably because vascular hyporeactivity improves after correction of volume depletion or treatment with NSAID. Extensive studies (reviewed in [137]) showed that this vascular hyporeactivity could be due to modifications in the angiotensin II-signaling. In turn, these modifications may prevent the release of free radicals – offering increased protection against cardiovascular remodeling in these patients [137]. Stoff et al. [138] evidenced a defect in platelet aggregation in four subjects with Bartter syndrome, but not in other hypokalemic patients. The platelet abnormality was exacerbated by restriction of dietary sodium and lessened by the administration of PG inhibitors. A circulating metabolite of prostacyclin, 6ketoPGE1, may be responsible for the defect [139].

Bartter syndrome is not classically associated with proteinuria. Kidney biopsies consistently show hyperplasia of the juxtaglomerular apparatus, with minimal or no glomerular or tubular abnormalities [1]. However, a few cases of cBS with proteinuria have been reported. Sardani et al. [140] described a 4-year-old African American child with a homozygous deletion in *CLCNKB* and mild mesangial proliferative glomerulonephritis consistent with C1q nephropathy. The follow-up studies of Bettinelli et al. [127] revealed mild-to-moderate glomerular proteinuria in 6/13

ClC-Kb-deficient patients. It was associated with decreased GFR in four patients and microhematuria in two. Kidney biopsy in two patients revealed diffuse or moderate mesangial hypertrophy [127]. In addition, a few cases of clinical BS with unknown genetic defect presented with focal segmental glomerulosclerosis (FSGS) and kidney failure [141, 142]. One of the patients described by Bartter developed CKD, with evidence of advanced nephrosclerosis, interstitial fibrosis, tubular atrophy, and glomerular hyalinization [143]. Causes of kidney failure in BS include complication of salt wasting (including long-standing hypokalemia, hypovolemic episodes, or nephrocalcinosis), chronic activation of the RAAS with ensuing stimulation of TGF-beta and/or TNF-alpha, and toxicity of NSAID [45, 140, 142]. Impaired kidney function was temporally associated with NSAID therapy in two cBS patients, with biopsy-proven interstitial nephritis and resolution after NSAID withdrawal [45]. However, the pathogenic role of NSAID in causing kidney damage in Bartter syndrome has been questioned by the nature and topology of the histological lesions, the fact that kidney lesions were identified in some patients before initiation of drugs, and the lack of progression of tubulointerstitial lesions over more than a decade under NSAID treatment [48, 144]. Of note, kidney cysts have been identified in patients with classic BS [40, 145], potentially linked to K^+ wasting and secondary aldosteronism [146].

Jeck et al. identified the common T481S variant in *CLCNKB*, which showed significantly increased currents when expressed in oocytes [147] and was associated with essential hypertension in a German cohort [148]. The relevance of these findings has been discussed [149], and linkage of the T481S variant to high BP was not confirmed in a Japanese cohort [150].

Differential Diagnosis, Unusual Associations, and Pseudo-Bartter Syndromes

The differential diagnosis of cBS includes the surreptitious use of loop diuretics, laxative abuse [151], which are both unusual in children [152], and chronic vomiting [153]. Measurement of urinary Cl^- and urine screen for diuretics are usually useful to diagnose these patients [154, 155].

The association of hypokalemic metabolic alkalosis with hyperreninemic secondary aldosteronism is also found in other familial disorders affecting the kidneys or the gastrointestinal tract or can be acquired. Generalized dysfunction of the proximal tubule (renal Fanconi syndrome), for instance, due to cystinosis [156], or Kearns-Sayre syndrome, a mitochondrial cytopathy caused by large deletions in mitochondrial DNA leading to cytochrome c oxidase deficiency [157], can be associated with biochemical features resembling BS. A case of familial kidney dysplasia with hypokalemic alkalosis has been reported [158]. Patients with cystic fibrosis are prone to develop episodes of hyponatremic, hypochloremic dehydration with metabolic alkalosis [159, 160]. As mentioned earlier, the Cl^-channel CFTR, which is mutated in cystic fibrosis, may regulate the function of ROMK in the TAL [78]. Gastrointestinal malformations which are associated with Cl^- deficiency [161], or Hirschsprung disease [162], can also lead to pseudo-Bartter syndrome. Administration of prostaglandins in neonates with a ductus-dependent congenital cardiopathy [163], aminoglycosides [164, 165] or combined chemotherapy [166] can induce the biochemical features of BS. Bartter syndrome has also been reported in association with autoimmune diseases, for instance, with Sjögren syndrome [167, 168]. Güllner et al. [169] described a syndrome of familial hypokalemic alkalosis in a sibship presenting with hyperreninemia, aldosteronism, high urinary prostaglandin E2 excretion, normal BP, and resistance to angiotensin II. At variance with BS, the patients had hypouricemia, indicative of proximal tubule dysfunction, and the fractional chloride reabsorption in the TAL was normal. The kidney biopsy showed hypertrophy of tubular basement membranes, whereas the juxtaglomerular apparatus was apparently normal. Finally, the association of BS with a partially empty sella detected by MRI of the brain has been reported in both adult and pediatric patients [170, 171].

Treatment

Patients with cBS are typically treated with PG synthetase inhibitors and escalating doses of KCl, complemented with K^+-sparing diuretics (most often, spironolactone) and NaCl in some of them [48, 127, 128]. Indomethacin is the most frequently used drug, usually started within the first 4 years of life at doses ranging from 1 to 2.5 mg/kg/d. Doses above 3 mg/kg/d are considered nephrotoxic. Indomethacin is well tolerated, but one should remain cautious for signs of gastrointestinal complications [40] or alteration of kidney function [45, 127]. Selective COX2 inhibitors, such as rofecoxib, have been used instead of indomethacin [40] and are currently being evaluated on a larger scale. Potassium supplementation (usually KCl, 1 to 3 mmol/kg/d) is mandatory in cBS, as hypokalemia is often severe at presentation and is not fully corrected by indomethacin [128]. If KCl alone fails to correct hypokalemia, then addition of spironolactone (1 to 1.5 mg/kg/d) is recommended. ACE inhibitors, which have been used for treating hypokalemia in adults with BS [172], should be used with caution given the risk of hypotension. Magnesium supplementation should be added when hypomagnesemia is present, but the correction is typically difficult [38]. Some patients with cBS require gastrostomy tube placement and enteral feeding [128].

The long-term efficacy of the standard treatment with indomethacin and KCl supplementation has been established in cBS. Most biochemical features improve with therapy, although K^+ levels are typically difficult to normalize in most patients despite NSAIDs, KCl, and spironolactone. Treatment also results in improved height and weight, but catch-up growth is inadequate and there is persistent height retardation [40, 48, 127, 128]. Growth hormone deficiency has been demonstrated in some patients, with a positive effect of recombinant human hormone treatment [127, 129]. As discussed above, some cases of cBS are complicated by CKD. A few cases of living-related kidney transplantation have been reported, with improvement of biochemical and hormonal abnormalities after transplantation [141, 144, 173].

Perioperative management of patients with cBS requires a particular care for volume repletion and correction of electrolyte abnormalities during anesthesia and the continuation of anti-prostaglandin therapy to prevent the defective platelet aggregation [174, 175].

Gitelman Syndrome

Genetics

Gitelman syndrome (GS) (MIM #263800) is generally considered as a milder disorder than BS and, with a prevalence of ~1 per 40,000 and potentially higher in Asia, arguably the most frequent inherited tubulopathy detected in adults [176]. The syndrome was first described in 1966 by Gitelman and coworkers as a familial disorder in which patients presented with hypokalemic alkalosis and a peculiar susceptibility to carpopedal spasm and tetany due to hypomagnesemia [177]. For more than 20 years, GS was assimilated with BS. In 1992, Bettinelli and coworkers concluded that GS could be distinguished from BS, based on low urinary Ca^{2+} excretion (molar urinary calcium/creatinine ratio less than or equal to 0.20) [178]. Also, BS patients were more often born after pregnancies complicated by polyhydramnios or premature delivery and had short stature, polyuria, polydipsia, and tendency to dehydration during infancy and childhood, whereas GS patients presented tetanic episodes or short stature at school age [178]. The dissociation of the tubular handling of Ca^{2+} and Mg^{2+} in GS, together with the subnormal response of these patients to thiazides [179, 180], pointed to a primary defect in the DCT.

In 1996, Simon and colleagues demonstrated that presumable loss-of-function mutations in the *SLC12A3* gene were responsible for GS [12]. *SLC12A3* is located on chromosome 16q13 and comprises 26 exons. It encodes the thiazide-sensitive Na^+-Cl^- cotransporter (NCC), a 1021 amino acid integral membrane protein expressed in the apical membrane of cells lining the DCT (Fig. 1). NCC belongs to the SLC12 family of electroneural cation-chloride coupled cotransporters that also includes the Na^+-K^+-$2Cl^-$ and the K^+-Cl^- cotransporters [181]. NCC contains a central hydrophobic region comprising 12 putative transmembrane domains flanked by a short

N-terminal and a long C-terminal hydrophilic intracellular terminus [182]. A model suggests that the affinity-modifying residues for Cl^- are located within TM 1 to 7 and for thiazides between TM 8 to 12 and that both segments are implicated in defining Na^+ affinity of the cotransporter [183]. The activity of NCC is regulated by posttranslational modifications such as glycosylation, phosphorylation, and ubiquitination. Glycosylation sites are found at the connecting loop between TM regions 7–8 (amino acids N406 and N426 in human); NCC is functional in a highly glycosylated homodimeric form. Phosphorylation of NCC is critical for maximal NaCl transport capacity and can alter NCC membrane abundance. Phosphorylation sites are found in the N-termini (amino acids T55, T60, S73, and S91). The phosphorylation of NCC is regulated by a variety of hormonal stimuli, which exert several of their effects via activation of the WNK-SPAK kinase cascade. Finally, NCC is regulated by ubiquitination via the aldosterone-SGK1-Nedd4-2 pathway; Nedd4-2 facilitates the degradation of non-phosphorylated NCC. In addition, it has been recently shown that Nedd4-2 inhibits the activity of the basolateral potassium channels Kir4.1/Kir5.1, which is associated with membrane depolarization and reduction of the driving force for Cl^- exit. The result is an increase of intracellular Cl^- concentration, which is known to inhibit WNK and SPAK. The final result is the inhibition of NCC phosphorylation and activity [183–186].

Gitelman syndrome is transmitted as an autosomal recessive trait, and the majority of patients are compound heterozygous for different mutations in *SLC12A3*. To date, more than 500 mutations scattered through *SLC12A3* have been identified in GS patients (http://www.hgmd.cf.ac.uk). Most (~53%) are missense mutations substituting conserved amino acid residues, whereas nonsense, frameshift, and splice-site defects and gene rearrangements are less frequent. A significant number of GS patients, up to 40% in some series, are found to carry only a single mutation in *SLC12A3*, instead of being compound heterozygous or homozygous [116, 187–189]. Because GS is recessively inherited, it is likely that there is a failure to identify the second mutation in regulatory fragments, 5′ or 3′ untranslated regions, or deeper intronic sequences of *SLC12A3* or that there are large genomic rearrangements. Nozu et al. were the first to report a deep intronic *SLC12A3* mutation in a GS patient, creating a new donor splice site that results in the inclusion of a novel cryptic exon in mRNA [190]. Lo et al. confirmed that deep intronic mutations in *SLC12A3* causing defective expression of NCC can be detected with an RNA-based approach in GS patients [191]. They suggested that analysis of cDNA from blood leukocytes to detect deep intronic mutations should be considered for GS patients who have undetectable or uniallelic *SLC12A3* mutations [191]. Recently, Nozu et al. identify the second variant in another GS patient using next-generation sequencing (NGS) technology; it was a deep intronic mutation creating a new acceptor splice site and inclusion of a cryptic exon [192]. Vargas-Poussou et al. showed that there is a predisposition to large rearrangements caused by the presence of repeated sequences within *SLC12A3*. These large rearrangements, which may account for up to 6% of all *SLC12A3* mutations, can be detected by multiplex ligation-dependent probe amplification (MLPA) or by NGS panels with read depth using adequate bioinformatic tools, enhancing the sensitivity of genetic testing to >80% [14, 116]. As discussed above, mutations in *CLCNKB* have been detected in a few patients presenting simultaneous features of cBS and GS [119, 130, 131] or phenocopying GS. In a cohort of 115 patients with *CLCNKB* pathogenic variants, 26% of cases had a Gitelman-like phenotype [13]. The distribution of ClC-Kb in both the TAL and DCT, and potential compensation by other Cl^- transporters, may probably explain these overlapping syndromes [2]. However, it is possible that other genes participate in the complex handling of Na^+, Ca^{2+}, and Mg^{2+} in DCT or its regulation phenocopying GS [193].

Pathophysiology

The functional effects of mutant NCC were tested using *Xenopus laevis* oocytes and in mammalian cells (HEK293 and MDCKI) [184, 189, 194–197]. Functional analyses revealed that some mutant NCC proteins were synthesized but not properly glycosylated or phosphorylated, targeted for degradation, and not delivered to the plasma membrane [194, 197]. Another class of *SLC12A3* mutations results in normal glycosylated proteins partly impaired in their routing and insertion that perform normal function once they reach the plasma membrane [195, 196]. Other mutants affect the intrinsic activity of the cotransporter, with normal glycosylation and plasma membrane insertion [189]. Finally, splicing mutations of *SLC12A3* result in truncated transcripts that trigger nonsense-mediated decay (NMD), a mRNA surveillance pathway that allows cells to degrade mRNA that contains premature translation stop codons [189]. Interestingly, missense mutation affecting exonic splicing enhancer (ESE) sequences can also cause exon skipping and premature termination [198]. Taken together, these results imply that GS may arise from impaired protein synthesis (splicing mutants); defective processing; defective protein insertion of functional mutants; and defective intrinsic activity of the mutant NCC in the DCT cells [189, 197, 199].

Schultheis and colleagues generated a mouse model with a null mutation in the *Slc12a3* gene on a mixed background [200]. The NCC-null mice showed hypocalciuria and hypomagnesemia at baseline but, in marked contrast to GS patients, no hypokalemic metabolic alkalosis. These mice had no signs of hypovolemia on a standard Na^+ diet, but they showed a lower BP than wild type when fed a Na^+-depleted diet for 2 weeks suggesting a subtle hypovolemia compensated at baseline. Subsequent studies performed on a homogeneous C57BL/6 strain showed that NCC-null mice had a mild compensated alkalosis with increased levels of plasma aldosterone [201] and an increased sensitivity to develop hypokalemia when exposed to dietary K^+ reduction [202]. Belge and coworkers showed that mice lacking parvalbumin, a cytosolic Ca^{2+}-binding protein that is selectively expressed in the DCT, had a phenotype resembling GS, with volume contraction, aldosteronism and K^+ loss at baseline, impaired response to hydrochlorothiazide, and higher bone mineral density [203]. They demonstrated that these modifications were due to modifications in intracellular Ca^{2+} signaling and decreased expression of NCC in the DCT [203].

Studies of inactivating *SLC12A3* mutations and mouse models indicate that the GS phenotype results from dysfunction of NCC. The functional loss of NCC in the DCT leads to salt wasting, volume contraction, stimulation of the RAAS, and increased excretion of K^+ and H^+ in the collecting duct resulting in hypokalemic metabolic alkalosis. By contrast, the pathogenesis of hypocalciuria and hypomagnesemia remains debated. Two hypotheses prevail respecting hypocalciuria. First, the volume contraction causes a compensatory increase in proximal Na^+ reabsorption, driving passive Ca^{2+} transport in the PT [204]. Second, the epithelial cells of the DCT hyperpolarize, due to lower intracellular Cl^- activity, which opens the apical voltage-dependent Ca^{2+} channels (TRPV5), resulting in increased Ca^{2+} influx and reabsorption [205]. Such hyperpolarization could also stimulate the basolateral Na^+/Ca^{2+} exchanger, further increasing Ca^{2+} reabsorption [206]. Studies performed in chronic hydrochlorothiazide-treated mice [207] favor the first hypothesis, as micropuncture experiments demonstrated increased reabsorption of Na^+ and Ca^{2+} in the proximal tubule, whereas Ca^{2+} reabsorption in the distal convolution was unaffected. Furthermore, micropuncture experiments performed in NCC-deficient mice revealed an enhanced fractional reabsorption of Na^+ and Ca^{2+} upstream of the DCT to compensate the transport defect in that segment [201]. The state of the extracellular fluid volume – substantially reduced or not – may also influence the type of tubular mechanism involved [208].

Hypomagnesemia is an essential feature of GS. Several mechanisms, including K^+ depletion, increased passive Mg^{2+} secretion, or defective active Mg^{2+} transport in the DCT, have been proposed to explain the Mg^{2+} wasting [4, 209]. The identification of TRPM6 as a Mg^{2+}-permeable channel in the DCT and its involvement in the pathogenesis of autosomal recessive hypomagnesemia (*see below*) suggested that this channel constitutes the apical entry step in active Mg^{2+} reabsorption [210]. Indeed, chronic thiazide administration increased Mg^{2+} excretion and reduced expression levels of TRPM6 in mice. In addition, TRPM6 expression was also drastically decreased in mice lacking NCC [207]. These results suggest that the pathogenesis of hypomagnesemia in chronic thiazide treatment as well as GS could involve TRPM6 downregulation. Structural variations in the epithelial cells lining DCT, with decreased absorptive surface area for Mg^{2+}, may also play a role [200, 211]. A study of NCC-deficient mice in the first weeks of life suggests that the shortening of the DCT in adult mice is probably the consequence of incomplete outgrowth of DCT1 during early perinatal kidney development [212]; this atrophy correlates with a marked reduction in the abundance of the TRPM6 channel. In addition, it has been suggested that hormonal pathways could co-regulate NCC and TRPM6 and that modifications of basolateral transport of Na and K may contribute to hypomagnesemia [213].

A large body of evidence has emerged that a complex signaling cascade involving a set of kinases (with no lysine kinases, WNK; sterile 20/SPS1-related proline/alanine-rich kinase, SPAK; oxidative stress-responsive kinase-1, OSR1) can activate members of the SCL12A family by phosphorylation of conserved Ser/Thr residues in their N-terminal domain. The importance of this pathway has been confirmed by the manifestations of GS caused by defective NCC and pNCC expression, observed in the SPAK-null mice generated by Yang et al. [214]. Using microarray studies, combined with biochemical, cell biological, and physiological phenotyping, Grimm and colleagues evaluated compensatory pathways in absence of NCC phosphorylation in SPAK-null mice. They showed an adaptatory network to increase salt reabsorption in several nephron segments including upregulation of Na transport in principal cells of connecting tubule and collecting ducts; upregulation of NaCl reabsorption in β-intercalated cells; remodeling of these segments to increase the number of principal and β-intercalated cells; and finally an increase of α-ketoglutarate (α-KG) production by proximal cells, which exercise a paracrine activity to increase NaCl reabsorption in β-intercalated cells [215].

Clinical Manifestations

Classically, GS was considered as a benign variant of Bartter-like syndromes, usually detected during adolescence or adulthood. Since the disorder originates from the DCT, the salt and water losses in GS patients are less pronounced than in aBS or cBS because urinary concentrating ability should not be affected (Table 2). The GS patients are often asymptomatic or present with mild symptoms such as weakness, fatigue, salt craving, thirst, nocturia, constipation, or cramps. They may also consult for growth retardation and short stature, reflecting an alteration in the growth hormone-insulin-like growth factor I axis or pleiotropic effects resulting from magnesium depletion [216]. Typical manifestations include muscle weakness, carpopedal spasms, or tetanic episodes triggered by hypomagnesemia [71, 217]. Blood pressure is reduced, particularly for patients with severe hypokalemia and hypomagnesemia [218]. However, high BP should not rule out the diagnosis, particularly in older patients. Indeed, mild hypertension has been repeatedly reported in GS patients [219, 220]. Since Mg^{2+} ions increase the solubility of calcium pyrophosphate crystals and are important for the activity of pyrophosphatases, hypomagnesemia may promote the formation of calcium pyrophosphate crystals in joints and sclera, leading to chondrocalcinosis [221] and sclerochoroidal calcifications [222]. Patients with GS have higher bone mineral density, similar to chronic thiazide treatment, which likely arises from increased Ca^{2+} reabsorption and a decreased rate of bone remodeling [223]. Potassium and Mg^{2+} depletion can prolong the duration of the action potential in cardiomyocytes and can result in prolonged QT interval, which could lead to an increased risk for ventricular arrhythmias. Prolonged QT interval was initially described in ~50% of the patients [224, 225]. However, in a recent study comparing GS patients with controls and using several ECG evaluations and an accurate method of measurement, the percentage of prolonged QT interval was 9%, although QT intervals in GS patients were longer than in controls [226]. The frequency of prolonged QT was even lower (1/90, 1.1%) in a large cohort of Japanese patients [227]. Cases of GS patient who presented with long runs of ventricular tachycardia [228] or ventricular fibrillation with favorable outcome after cardioversion and continuous supplementation [229] have been reported. In addition, hypokalemic rhabdomyolysis has been reported in several (BS and) GS patients [230–232]. Pregnancies in GS appear to have a favorable outcome, provided continuous K^+ and Mg^{2+} supplementation and monitoring for oligohydramnios [233, 234]. A summary of the manifestations associated with GS and their frequency is shown in Table 3.

Several case reports associating autoimmune disease and genetically confirmed GS have been described [235–240]. In these cases the thyroid is often the affected organ. In a large cohort of Japanese GS patients, the prevalence of thyroid dysfunction was 4.4% [227]. Evans et al. investigated immunity in a group of patients with salt-losing tubulopathies (SLT) including 22 patients with GS [241]. They reported increased bacterial and fungal infections, increased prevalence of eczema/dermatitis and allergic disease, and the presence of autoimmune phenomena in 30% of their SLT cases. Using 23Na-MRI, they demonstrated that sodium stores are reduced in SLT patients compared to controls, which impacts T cell polarization and impairs IL-17 responses, leading to immunodeficiency. This phenotype is comparable with pattern observed in patients with IL-17 deficiency secondary to hereditary anomalies in the transcription factors STAT1/3 (chronic mucocutaneous candidiasis/Hyper-IgE recurrent infection syndrome). Moreover, they confirmed that the addition of NaCl to Th17 lymphocytes rescued polarization and IL-17 production, raising the possibility that correction of extracellular ionic concentrations in SLT patients may mitigate infection risk.

Another clinical manifestation described in GS patients is vertigo. In a French cohort, vertigo without orthostatic hypertension was described in 22% (20/90) of cases [242]. In this study, an adapted questionnaire and complete neuro-ontological exam in 16 cases showed that vertigo was of short duration and triggered in half of patients by head rotation. Seven patients had a vestibular syndrome. Five patients had associated auditory signs (tinnitus, aural fullness, or hearing loss). The expression of NCC in the medial part of the endolymphatic sac in the inner ear [243] and the frequency of vestibular disorder in GS patients (7/90, 8%) suggest a role of NCC in the regulation of endolymphatic composition and/or volume.

The classical biological features of GS include hypokalemic metabolic alkalosis, hypomagnesemia, and hypocalciuria. The recently published consensus [176] proposed the following criteria for suspecting a diagnosis of GS: documented chronic hypokalemia (<3.5 mmol/l) concomitant with inappropriate potassium wasting (spot urine, potassium-creatinine ratio >2.0 mmol/mmol [>18 mmol/g]), in absence of potassium-lowering drugs; metabolic alkalosis; hypomagnesemia (<0.7 mmol/l [<1.70 mg/dl]); inappropriate magnesium wasting 19 (fractional excretion of magnesium >4%); hypocalciuria (spot urine, calcium-creatinine ratio <0.2 mmol/

Table 3 Clinical manifestations associated with Gitelman syndrome

Most common (> 50% of patients)	Prominent (20 to 50% of patients)	Occasional (Less than 20%)	Rare (Case reports)
Salt craving Cramps, muscle weakness, pain Fatigue Dizziness Nocturia Thirst, polydipsia Paresthesia, numbness Palpitations Low blood pressure	Fainting Polyuria Arthralgia Chondrocalcinosis Prolonged corrected QT interval Febrile episodes	Early onset (before age 6) Failure to thrive Growth retardation Vertigo, ataxia Carpopedal spasm, tetany Vomiting Constipation Enuresis Paralysis	Seizure Ventricular tachycardia Rhabdomyolysis Blurred vision Pseudotumor cerebri Sclerochoroidal calcifications

mmol [<0.07 mg/mg]) in adults; calcium-creatinine ratio in children should be interpreted according to age [244]; high renin (activity or plasma levels); fractional excretion of chloride >0.5%; normal or low BP; and normal renal ultrasound with absence of nephrocalcinosis or kidney abnormalities. The presence of both hypomagnesemia and hypocalciuria is highly predictive for the diagnosis of GS [178]. However, there are inter- and intra-individual variations in the extent of hypocalciuria, and hypomagnesemia may be absent in some patients [2, 38, 245]. In the large Japanese cohort described by Fujimura et al., 45% of GS cases showed normal serum magnesium level, and a higher values were observed in GS patients harboring hotspots variants [227]. In addition, the combination of hypocalciuria and hypomagnesemia is also detected in rare cases of cBS patients [130]. Although the urinary PGE_2 excretion is classically normal in GS, increased values of PGE2 or its metabolites can also be detected in some patients with GS [2, 246]. Recently, Vigano et al. showed a hitherto unrecognized tendency toward phosphate wasting with mild to moderate hypophosphatemia that is not related to an altered circulating level of either 25-hydroxyvitamin D or parathyroid hormone [247]. Interestingly, studies in the mouse model of GS showed high FGF23 and PTH levels without modifications of 1,25(OH)2D3, fractional phosphate excretion, and expression of the NaPi2a cotransporter, the FGFR1 receptor, and the co-receptor Klotho. The FGF23 levels were decreased by eplerenone indicating that FGF23 upregulation is aldosterone-mediated [248]. Further studies are necessary to determine whether FGF23 is increased in GS patients with hypophosphatemia.

Several studies described abnormal glucose metabolism and insulin secretion, as well as an increased risk for the development of type 2 diabetes in GS patients, probably due to hypokalemia and hypomagnesemia [249–251]. In the Chinese cohort described by Liu et al., 48% of GS patients had abnormal glucose metabolism and 21% had type 2 diabetes [238]. In the cross-sectional study published by Blanchard et al., GS patients had resistance to insulin potentiated by high BMI, 14% of GS patients having a prediabetes status. The subgroup of GS patients with severe hypomagnesemia had higher insulin resistance index and a tendency toward higher BMI irrespective of the presence of severe hypokalemia, suggesting that magnesium depletion is the predominant contributor to insulin resistance [252]. To decrease risk of diabetes in patients with GS, both low glucose diet and prevention of weight gain are recommended.

No specific findings are observed at kidney biopsy, apart from occasional hypertrophy of the juxta-glomerular apparatus and markedly reduced expression of NCC by immunohistochemistry [253]. Interestingly, a few cases of GS associated with glomerular abnormalities and/or proteinuria have been described. Focal segmental glomerulosclerosis was described in a 21-year-old patient who underwent a biopsy for evaluation of chronic hypokalemia [254]. Hanevold et al. [255] reported a case of focal segmental glomerulosclerosis and C1q nephropathy in an African American child with GS who subsequently developed nephrotic range proteinuria. Another case of focal segmental glomerulosclerosis was reported by Ceri et al. in a 32-year-old man with GS and persistent proteinuria [256]. A retrospective analysis of GS patients revealed proteinuria with preserved kidney function in 6/36 patients. Three of these six patients presented hypertension. No kidney biopsy was performed [220]. Demoulin et al. reported a case of genetically proven GS with glomerular proteinuria and significant abnormalities of the glomerular basement membrane (GBM). Interestingly, defects of the GBM and podocytes were also detected in the *Slc12a3* KO mouse model [257]. These observations point to the possible link between the functional loss of NCC and podocyte dysfunction, potentially due to angiotensin II- or renin-induced podocyte lesions or to chronic hypokalemia [257].

Phenotype Variability and Potential Severity of GS

The view that GS is a benign condition has been challenged by reports emphasizing the phenotype variability and the potential severity of the disease. An evaluation of 50 patients with identified

SLC12A3 mutations revealed that GS is associated with a significant reduction in the quality of life – similar to that associated with congestive heart failure or diabetes [258]. Manifestations such as early onset (before age of 6), growth retardation, invalidating chondrocalcinosis, tetany, rhabdomyolysis, seizures, and ventricular arrhythmia have been described, although in a limited number of cases [38, 189, 216, 228, 258]. Using a standardized questionnaire, quality of life was evaluated in 11 patients with SLT, including 9 GS patients, and the results correlated with biochemical parameters [259]. Higher plasma aldosterone levels were correlated significantly with higher limitations due to physical health; whereas higher magnesium was significantly correlated with better mental health.

Chronic hyperaldosteronism seems to not have effect on cardiac function in GS patients. A recent study analyzed global left ventricular mass index and intracellular and extracellular mass index using cardiac magnetic resonance in patients with different etiologies of hyperaldosteronism [260]. Four groups of 20 individuals with primary aldosteronism, essential hypertension, GS, and healthy control were compared. Only primary aldosteronism combined with high BP increased both extracellular myocardial matrix and intracellular mass. Secondary aldosterone excess with normal BP, i.e., the situation in GS patients, did not affect extracellular myocardial matrix, a measure of myocardial fibrosis in vivo.

The phenotype of GS is highly heterogeneous in terms of age at presentation, gender, biochemical abnormalities, and clinical manifestations (Table 3). The phenotype variability has been documented not only between patients carrying different *SLC12A3* mutations but also for a common underlying mutation [261] and between affected family members [189, 262]. In Chinese cohorts, females have a less severe phenotype than males [238, 234, 246]. The mechanisms that could account for intrafamilial variability include gender (affected brothers are apparently more severely affected than their sisters carrying the same mutation), modifier genes (affecting the regulation or activity of NCC), and environmental factors (dietary intake of NaCl, Ca^{2+}, or Mg^{2+}) [2, 189, 262, 263]. Compensatory mechanisms operating in other nephron segments should also be considered, as evidenced in mice with defective NCC [201, 203, 207]. Considering that most of patients with GS are compound heterozygous harboring various mutant *SLC12A3* alleles, the phenotype variability could be related to the nature and/or position of the underlying mutation(s). This hypothesis has been substantiated by the studies of Riveira-Munoz et al. [189] which showed that a specific combination of mutations was preferentially associated with a severe presentation of GS. Balavoine et al. showed a more severe phenotype in GS patients with two mutated alleles than in those with one or no mutated alleles [219]. A follow-up study in a large cohort of 117 Taiwanese GS patients demonstrated that male patients had an earlier age of onset, more severe hypokalemia, and significantly lower serum aldosterone concentration and that patients with homozygous and deep mutations in intron 13 had a more severe phenotype [250]. Conversely, Berry et al. reported an apparently more severe electrolyte disturbance in women, which could possibly be due to the effects of female hormones on expression or function of NCC [220].

Blood Pressure in GS: Effect of the Carrier State

In 2001, Cruz et al. investigated a large Amish kindred to show that patients with GS had significantly lower age- and gender-adjusted diastolic and systolic BP, a higher urinary Na^+ excretion, and a higher salt intake than their unaffected relatives [218]. Additional support for the role of NCC in BP regulation was provided by the report that transplantation of a GS kidney into a non-Gitelman hypertensive recipient resulted in the correction of hypertension in the latter [264]. Considering that the frequency of heterozygote carriers of *SLC12A3* mutations varies from 1% to 4% [265, 252], the question was thus raised whether single loss-of-function mutations in *SLC12A3* may affect BP regulation in the general population [54]. Lifton and colleagues screened

3125 adult subjects from the Framingham Heart Study for mutations in *SLC12A3* (and by extension *SLC12A1*, and *KCNJ1*, responsible for aBS) and identified 30 different mutations in *SLC12A3*, 10 in *SLC12A1*, and 5 in *KCNJ1*) in 49 subjects [52]. Of these mutations, 10 were biochemically proven loss of function (7 in NCC alone), and 20 were inferred from the conservation and rarity criteria. Examination of long-term BP revealed that 80% of the mutation carriers were below the mean systolic BP values of the entire cohort. The mean BP reduction in carriers was similar to values obtained with chronic thiazide treatment [52]. This study was replicated in a population of 7444 European ancestry individuals from the Atherosclerosis Risk in Communities study [266].

The studies described above analyzed a small number of individuals from very large unselected cohorts using office BP evaluation. To better evaluate the phenotype of heterozygous carriers of *SLC12A3* mutations, Blanchard et al. performed a cross-sectional study comparing 81 heterozygous carriers, 82 healthy noncarriers, and 79 patients with GS of similar age, body mass index, and sex ratio [252]. In this study the heterozygous patients were relatives of GS patients, BP was evaluated by home monitoring, and biochemical analyses included oral glucose tolerance testing and assays of plasma and urine electrolyte and hormone levels. They failed to confirm a protective effect against hypertension in heterozygous carriers although a subtle intermediate phenotype, characterized by a slightly increased plasma aldosterone, slightly higher plasma calcium, and lower plasma PTH concentrations compatible with an increase in reabsorption of calcium, was observed. Thus, larger studies are required to confirm a phenotype associated with the carrier state of GS.

Differential Diagnosis

The differential diagnosis of GS includes other Bartter-like syndromes (Tables 1 and 2) and particularly cBS due to mutations in *CLCNKB* [2, 245], as well as diuretic or laxative abuse, and chronic vomiting. As mentioned above, the clinical history and biochemical features, even hypocalciuria and hypomagnesemia, may not be fully reliable to distinguish GS from cBS. In the clinical setting, the evaluation of the response to hydrochlorothiazide (HCTZ test) offers a high sensitivity and specificity for the diagnosis of GS [245, 267]. However, in view of the rapid progress of genetic testing, HCTZ test is no longer recommended as a diagnostic tool in GS because of the related risks: when it is used diagnostically there is a risk of acute volume depletion in subjects with loop of Henle defect [268, 176]

Patients with molecular anomalies in the *HNF1B* gene coding for transcription factor HNF1β can mimic GS. Hypomagnesemia, hypokalemia, and hypocalciuria can be present in *HNF1B*-related disorders [269, 270]. In the recent study in the UK cohort, hypomagnesemia was constant when evaluated in the second decade of life [271]. HNF1β has been shown to regulate expression of the γ-subunit of the basolateral Na^+-K^+-ATPase (FXYD2) and the basolateral potassium channel kir5.1, which in turn regulates the activity of the Na^+-K^+-ATPase, which is crucial for the transport activity in the DCT [272, 273]. The presence of a family history, dominant mode of inheritance, maturity onset diabetes of the young, chronic kidney disease, and other renal and extrarenal anomalies described in *HNF1B*-related disorders can help to orientate the diagnosis [274].

Patients with pathogenic variants in the *FXYD2* gene were described as a cause of isolated hypomagnesemia; however, subsequent data on newly discovered patients also show a trend to a Gitelman-like tubulopathy [275]. This is in agreement with the known pathophysiology of HNF1β as transcription factor.

Mutations in the *KCNJ10* gene coding for the inwardly rectifying potassium channel Kir4.1 cause EAST syndrome, an autosomal recessive disorder characterized by epilepsy, ataxia, sensorineural deafness, and tubulopathy with the same characteristics of GS [276, 277]. Kir4.1 forms heterodimers with Kir5.1 channel, which regulate the activity of the basolateral Na^+-K^+-ATPase. The extrarenal features of EAST syndrome allow it to be distinguished from GS.

Nowadays, the use of high-throughput sequencing is recommended for diagnosis of GS [176]. It allows the analysis at the same time of genes phenocopying GS included in specific panels [14, 278] or in the future the analysis of in silico panels after whole exome or whole genome sequencing.

Gitelman syndrome-like manifestations including hypokalemic metabolic alkalosis with hypomagnesemia and hypocalciuria have been reported as a rare complication of the use of cisplatin [279]. Although the mechanism remains uncertain, cisplatin is known to induce focal tubular necrosis lesions in the DCT [280]. Autoimmune disorders cause acquired kidney tubular disorders, potentially due to autoantibodies against tubular components [281]. Typical features of acquired GS have been reported in association with various autoimmune disorders including iritis and arthritis [282], sialoadenitis [168], and Sjögren syndrome [283]. Of note, there was no improvement of K^+ wasting after corticosteroid treatment in one such case [283].

Treatment

Because GS is caused by a primary defect in a NaCl cotransporter, ad libitum NaCl intake should be strongly advocated. It is recommended to encourage patients to follow their propensity for salt consumption ("salt craving") [176]. Lifelong oral magnesium and potassium supplementations are the main treatment in patients with GS. A reasonable target for potassium may be 3.0 mmol/l and magnesium 0.6 mmol/l (1.46 mg/dl) [176]. Magnesium supplementation should be considered first, since Mg^{2+} repletion will facilitate K^+ repletion and reduce the risk of tetany and other complications related to hypomagnesemia [217, 220, 284]. All types of magnesium salts are effective, but their bioavailability is variable. Magnesium chloride, magnesium lactate, and magnesium aspartate show higher bioavailability [217]. $MgCl_2$ is recommended since it will also correct the urinary loss of Cl^-. The dose of magnesium must be adjusted individually in three to four daily administrations, with diarrhea being the limiting factor. The recommended starting dose is 300 mg/day (12.24 mmol) of elemental magnesium (5 mg/kg in children, i.e., 0.2 mmol/kg), in slow-release tablets when possible. In addition to magnesium, high doses of oral KCl supplements may be required; starting doses could be ≥40 mmol KCl (1–2 mmol/kg in children), in divided doses throughout the day [285]. Importantly, Mg^{2+} and K^+ supplementation results in a catch-up growth [189, 216]. Spironolactone or amiloride can be useful, both to increase serum K^+ levels in patients resistant to KCl supplements and to treat Mg^{2+} depletion that is worsened by elevated aldosterone levels [286]. Both drugs should be started cautiously to avoid hypotension. Patients should not be refrained from their usual salt craving, particularly if they practice a regular physical activity. More recently, the potassium-sparing diuretic and aldosterone antagonist eplerenone was shown to be useful in the treatment of GS patients [287–290]. Eplerenone is a selective aldosterone antagonist, with significantly lower affinity for androgen, progesterone, and glucocorticoid receptors in comparison with spironolactone and has therefore no anti-androgenic side effects (such as gynecomastia, hirsutism, erectile dysfunction, and menstrual irregularities) [287]. The usefulness of eplerenone was initially demonstrated in patients with cardiovascular disease and heart failure [291]. Prostaglandin inhibitors such as indomethacin are less indicated in GS than in aBS, since urinary PGE_2 levels are usually normal. Liaw et al. reported an improvement in growth response following high-dose indometacin but complicated by gastrointestinal hemorrhage [292]. Refractory hypokalemia has also been treated with the specific COX-2 inhibitor rofecoxib [293]. Considering the occurrence of prolonged QT interval in GS patients [224, 225], QT-prolonging medications should be used with caution. An open-label, randomized, crossover study was conducted to compare the efficacy and safety of 6-week treatment with one time daily 75 mg slow-release indomethacin, 150 mg eplerenone, or 20 mg amiloride added to constant potassium and magnesium supplementation in 30 GS patients [290]. Each drug increased plasma potassium concentration.

Indomethacin was the most effective, but it was associated with decreased eGFR, and it can cause gastrointestinal intolerance. Amiloride and eplerenone had similar but lower efficacies and increased sodium depletion [290].

Caution should be taken when patients with GS undergo anesthesia because the effects of local and general anesthetic agents can be potentiated by hypokalemia and hypomagnesemia. Although exact and safe preoperative levels of potassium and magnesium have not been established, the UK National Institute for Health and Care Excellence (NICE)-approved guidelines suggest aiming for potassium levels of ≥3.0 mmol/l and magnesium 0.5 mmol/l (1.22 mg/dl) [294].

Although GS adversely affects the quality of life [258], we lack information about the long-term outcome of these patients. Kidney function and growth appear to be normal, provided lifelong supplementation [295]. Progression to kidney failure is rare in GS: only two patients with GS who developed end-stage kidney disease have been reported [296, 297]. However, in the follow-up study of a large cohort of 117 Taiwanese patients, 7/117 (6%) patients developed CKD (stage III-IV) and 5/117 (4.3%) patients developed type 2 diabetes at follow-up (mean duration, 6.7 ± 3.4 years; range, 1–33 years [250]. In addition, despite the salt wasting, development of secondary hypertension may be expected in the aging GS population [220]. In view of recent results, both low glucose diet and prevention of weight gain are recommended in patients with GS to decrease risk of diabetes [176].

Pseudohypoaldosteronism Type I

Type 1 pseudohypoaldosteronism (PHA1) is a rare form of mineralocorticoid resistance characterized by neonatal kidney salt wasting, failure to thrive, and dehydration. It is associated with hyponatremia, hyperkalemia, and metabolic acidosis, despite extremely high values of plasma renin and aldosterone [298]. It was first reported by Cheek and Perry, who described a male infant with severe salt wasting in the absence of any renal or adrenal defect [299]. There exist two different clinical forms of PHA1: (i) a dominantly inherited form, in which mineralocorticoid resistance is restricted to the kidney, and (ii) a recessively inherited form, where mineralocorticoid resistance is systemic and salt loss occurs in multiple organs [300].

Clinical and Biochemical Features

Autosomal dominant PHA1 (MIM#177735, or PHA1A) is a mild form and represents the most frequent form of the disease [301]. The prevalence, as estimated from recruitment through a national reference center for rare diseases (MARHEA, http://www.soc-nephrologie.org/marhea/) is ~1 per 80,000 newborns. Clinical expression is variable: in general, patients show a salt-losing syndrome in the neonatal period, with weight loss, failure to thrive, vomiting, and dehydration. Occasionally, patients may also present hypercalciuria. Biological findings are hyponatremia, hyperkalemia, and inappropriately high urinary sodium excretion. In contrast, urinary potassium excretion is low, with reduced fractional potassium excretion and transtubular potassium gradient [302, 303]. The diagnosis is confirmed by the presence of high plasma and urinary aldosterone and high plasma renin levels. Symptoms of PHA1A usually improve in early childhood. The mechanisms which restore sodium homeostasis in these patients are not clear; most likely, kidney maturation, access to dietary salt, compensatory increase in proximal sodium reabsorption, as well as the upregulation of the mineralocorticoid axis all play a role to compensate for the distal salt loss. A recent case-control study, comparing 39 adult patients with PHA1A carriers of *NR3C2* mutations with sex- and age-paired noncarriers, showed that adult PHA1A subjects present lifelong increased plasma renin and aldosterone levels together with increased salt appetite, with normal potassium levels and BP [304].

Autosomal recessive PHA1 (MIM #264350, or PHA1B), is characterized by severe salt wasting from the kidney, colon, sweat, and salivary glands

[305]. Patients present in the neonatal period with severe dehydration, vomiting, and failure to thrive; acute polyhydramnios has been described [306] but seems exceptional. The clinical picture may be complicated by cardiac dysrhythmias, collapse, shock, or cardiac arrest [307]. Severe hyperkalemia and high aldosterone and plasma renin levels orient the diagnosis that can be completed by a positive salivary or sweat test. Consistent with the systemic mineralocorticoid unresponsiveness, patients present elevated sweat and salivary Na^+ and Cl^- and absent nasal amiloride-sensitive Na^+ transport [300]. In addition to the kidney phenotype, frequent respiratory tract illnesses have been observed, characterized by persistent rhinorrhea of clear liquid, congestion, tachypnea, wheezing, frequent fever, and recurrent pulmonary infections, evoking cystic fibrosis, due to their reduced capacity to absorb liquid from airway surfaces [308]. Also, the high concentration of sweat salt may cause inflammation and damage in the eccrine structures, with cutaneous lesions similar to those appearing in miliaria rubra [307, 309]. PHA1B is more severe than the dominant form (PHA1A), and the prognosis is poor: no remission has been reported and patients suffer from recurrent life-threatening episodes of salt loss. Early diagnosis within the first week of life is critical to survival in generalized PHA1B [310].

Secondary PHA1. Transient pseudohypoaldosteronism has been observed in infants less than 7 months of age suffering from urinary tract malformations or urinary tract infections or both [311, 312]. The incidence has been estimated around 1 per 13,200 total live births per year [313]. Any kind of congenital urinary tract obstruction (ureterohydronephrosis, ureterocele, ureteropelvic junction obstruction, posterior urethral valves) may lead to secondary PHA1. Physiopathological mechanisms responsible for transient PHA1 are poorly understood, but the gravity of the salt wasting is inversely correlated with age, supporting a role for tubular immaturity [310]. In these patients, medical or surgical cure of the primary disease reestablishes the normal response to aldosterone although high salt intake is recommended in the acute phase with progressive tapering. The possibility that a transient tubular mineralocorticoid resistance can arise in infants with urinary tract malformations or urinary tract infections strongly supports an indication for renal ultrasonography and urine cultures in all children presenting with salt wasting and hyperkalemia [311]. Secondary PHA1 may also develop in adults following resection of the ileum and colon [314] or in patients with kidney transplantation treated with immunosuppressants (tacrolimus, cyclosporine), probably due to impairment of the mineralocorticoid receptor transcriptional activity [315].

Pathophysiology and Genetics

Aldosterone plays a key role in electrolyte balance and BP regulation. It confers the main hormonal regulation of sodium, potassium, and hydrogen balance in the aldosterone-sensitive distal nephron through its interaction with the mineralocorticoid receptor [316] (Fig. 3). The MR belongs to the nuclear receptor superfamily and acts as a ligand-activated transcription factor regulating expression of a coordinate set of genes ultimately eliciting physiologic aldosterone responses [317]. In the collecting duct, aldosterone stimulates activity of several proteins implicated in transepithelial Na^+ transport, including ENaC and Na^+-K^+-ATPase [318].

Since the first description of PHA1, a defect of the tubular response to aldosterone had been suggested as the underlying cause. After the characterization of aldosterone binding sites in mononuclear leukocytes, Armanini et al. confirmed this hypothesis by showing that ^3H-aldosterone binding was absent or very low in mononuclear leukocytes of affected patients [319]. In a subsequent study of eight families, a dual pattern of inheritance was observed that correlated with receptor binding abnormalities. In some families, an autosomal recessive inheritance of the disease was observed, and binding studies and aldosterone levels were normal in both parents. In contrast, some families presented with an autosomal dominant inheritance, and low receptor number and elevated plasma aldosterone were always found in one of the parents [320]. The main differences between the dominant (PHA1A) and recessive

Fig. 3 Molecular basis of pseudohypoaldosteronism type I. Aldosterone binds to its intracellular receptor, the mineralocorticoid receptor (MR). Hormone binding induces dissociation of MR-associated proteins and translocation of the aldosterone-receptor complex into the nucleus, where it binds to specific DNA sequences in regulatory regions of hormone-responsive genes. These genes code for proteins involved in transepithelial sodium transport (the epithelial sodium channel, ENaC; the sodium-potassium pump Na,K-ATPase), for regulatory proteins (serum- and glucocorticoid-regulated kinase 1 (sgk1), channel-inducing factor (CHIF), the proto-oncogene K-Ras2, N-myc downregulated gene 2 (NDRG2)) and others. Apical and basolateral indicate the two poles of the epithelial cell. *Abbreviations*. Aldo: aldosterone

(PHA1B) forms of PHA1 are summarized in Table 4.

Subsequently it was shown that the two clinical forms of PHA1 were caused by different genetic defects. Inactivating mutations in the *NR3C2* gene coding for the MR are found in PHA1A [321–323]. The human MR coding gene *NR3C2* spans over ~450 kB on chromosome 4p31.23 and is composed of ten exons [324]. Patients are heterozygous carriers of genetic variants which can be found in both patients with autosomal dominant PHA1A and patients with a sporadic renal presentation [323]. In the latter group, only one-third are *de novo* mutations, implying that carriers develop clinically evident disease only in a small proportion of kindreds. Although the exact causes for the variable phenotypic expression of PHA1A are unknown, intercurrent events, such as infections, vomiting, and diarrhea, may precipitate neonatal salt loss and dehydration in individuals at risk. Also, naturally occurring hypomorphic or hyperfunctioning alleles of other genes, coding for proteins involved in distal sodium reabsorption, may aggravate or attenuate the phenotype.

Table 4 Distinctive clinical and biological features of renal and generalized PHA1

Feature	Autosomal dominant PHA1 (PHA1A)	Autosomal recessive PHA1 (PHA1B)
OMIM	#177735	#264350
Age of onset	Neonatal	Neonatal
Phenotype	Mild	Severe
Failure to thrive	Present	Present
Vomiting	Present	Present
Dehydration episodes	Mild	Severe
Cardiac dysrhythmias, collapse, shock, or cardiac arrest	No	Sometimes
Respiratory tract illnesses	No	Frequent
Eczematoid rash of the skin	No	Sometimes
Hyperkalemic metabolic acidosis	Present	Present
Serum Na^+	↓	↓
Serum K^+	↑	↑
Urinary Na^+ excretion	↑	↑
Urinary Ka^+ excretion	↓	↓
Plasma aldosterone	↑	↑
Plasma renin	↑	↑
Urinary aldosterone	↑	↑
Sweat Na^+	N	↑
Salivary Na^+	N	↑
Type of mutation	Loss of function	Loss-of-function
Gene locus	4q31.1	12p13, 16p13-p12, 16p13-p12
Genes	*NR3C2*	*SCNN1A*, *SCNN1B*, *SCNN1G*
Proteins	MR, mineralocorticoid receptor	α-, β-, γ-subunits of the epithelial Na^+ channel ENaC

After the first description of *NR3C2* mutations in four dominant and one sporadic case of PHA1A [321], more than 100 different causal genetic variants have been reported in patients with PHA1A [325]. Disease-causing variants are located in all exons of the *NR3C2* gene, affecting all functional domains of the MR protein. However, only frameshift, splice site, and nonsense mutations were reported in exon 2, suggesting that missense mutations affecting the N-terminal domain do not sufficiently affect MR function to become clinically apparent.

The pathogenic mechanism of PHA1 in patients with heterozygous MR mutations depends on the mutation. Although haploinsufficiency is sufficient to cause autosomal dominant PHA1A [322, 326], mutated receptors may also exert dominant negative effects on the wild-type receptor since MR regulate transcription by binding as receptor dimer to regulatory regions of target genes [322]. In this case, effects of mutated receptors are strongly promoter-dependent and may differentially affect MR function in a gene-specific manner [327, 328]. Furthermore, the same mutation may induce complete functional loss of transcriptional activity on one promoter while retaining a partial transcriptional activity on another gene [328]. Thus, not only the extent of functional reduction but also the specific qualitative loss of function, in terms of regulated gene expression, modulate the phenotype in PHA1 patients with *NR3C2* mutations.

The severe and generalized, recessive form of PHA1 (PHA1B) is caused by loss-of-function mutations of the genes coding for the subunits of the amiloride-sensitive sodium channel ENaC (*SCNN1A*; *SCNN1B*; *SCNN1G*). ENaC is a hetero-multimeric protein composed of three subunits, α, β, and γ, which form the channels expressed on the cell surface (see review by

479 [329]. The α-subunit of ENaC is encoded by *SCNN1A* located on chromosome 12p13.3, whereas *SCNN1B* (encoding βENaC) and *SCNN1G* (encoding γENaC) are located within 400 kb on chromosome 16p12.2-p13.11. Loss-of-function mutations have been found in affected patients being either homozygous – in consanguineous families – or composite heterozygous [330, 331]. They include missense and nonsense mutations, deletions, insertions, and splice site junction mutations leading to abnormal mRNA splicing. PHA1B-causing variants appear in all ENaC subunits but are more frequent in the α-subunit, consistent with its determinant role in channel function. Missense mutations are found in critically important domains of the protein and affect functions like intracellular trafficking of the channel, channel gating, or the ion-selectivity filter [332].

Genotype-phenotype correlations are not well established in PHA1B. One study has explored the long-term consequences of different αENaC mutations on the renin-aldosterone system, growth, and pubertal development of PHA1B patients [333]. Three patients homozygous for nonsense and frameshift mutations in αENaC presented short stature, poor growth, and growth hormone tests compatible with the diagnosis of GH deficiency. In all patients, there was an age-dependent normalization in the urinary Na/K ratios accompanied by an exaggerated renin-aldosterone system response probably contributing to age-dependent amelioration. In contrast, one patient compound heterozygous for a missense mutation and for a frameshift mutation of αENaC presented normal growth, normal puberty, and decrease of renin-aldosterone axis activity with age. These results demonstrate distinct genotype-phenotype relationships in PHA1B patients that depend on the degree of functional ENaC impairment. If undetected during the first week of life, multi-system PHA1B can lead to neonatal death; however, if detected, the patients may lead near normal lives on a lifelong high-salt diet [334].

Extensive genetic investigation of PHA1 patients in recent years has also shown that the disease comprises a continuum of phenotypically and/or biologically distinct entities that may challenge the current genetic classification of the disease. Indeed, investigation of heterozygote carriers of a αENaC p.Ser562Pro mutation, responsible for PHA1B in homozygous patients, revealed a subclinical salt-losing phenotype with increased sweat sodium and chloride concentrations without additional hormonal or clinical manifestation [335]. Furthermore, recessively inherited ENaC mutations, associated with partial loss of channel function, may result in a mild phenotypic expression of PHA1B, with a salt-losing disorder in a premature infant, but only a biological phenotype in a sibling born at term [336]. We also observed a case of recessive PHA1A with an extremely severe phenotype of dehydration and hyperkalemia, but without cutaneous or pulmonary phenotype, caused by MR mutations [337]. These cases broaden the spectrum of clinical phenotypes in PHA1A and support corresponding genetic screening for the disease in patients with isolated renal salt-losing syndromes and/or failure to thrive.

Treatment and Prognosis

Treatment of PHA1 consists in the replacement of salt loss and rehydration, as well as correction of hyperkalemia and acidosis in the acute phase of the disease. Since the main differential diagnosis is congenital adrenal hyperplasia or isolated deficiency in aldosterone synthase (CMOI and CMOII) [338], replacement therapy with fludrocortisone and hydrocortisone may be undertaken while confirming the diagnosis by hormonal measurements. Early postnatal hyperkalemia may sometimes complicate antenatal Bartter's syndrome (aBS, due to mutation in the potassium channel ROMK) [51]. Its association with hyponatremia and hyperreninemic hyperaldosteronism may erroneously suggest the diagnosis of PHA1. However, hyperkalemia appears usually very early and normalizes by the end of the first postnatal week, whereas secondary PHA1 is characterized by permanent hyperkalemia. Other distinctive features of aBS patients are metabolic alkalosis as well as hypercalciuria and nephrocalcinosis. Also maternal hydramnios, present in aBS, is a rare event in generalized PHA1.

After the acute period, treatment consists in salt supplementation. The doses vary depending on the severity of the disease. Neonatal genetic diagnosis on cord blood may allow rapid diagnosis and management of the condition in affected offspring from PHA1 families with identified mutations. In PHA1A and secondary PHA1, 3–20 mEq/kg/d of Na+ given as NaCl and NaHCO3- are sufficient to compensate for the salt loss and are followed by rapid clinical and biochemical improvement. The expansion of extracellular volume results in increased tubular flow and delivery of sodium to the distal nephron, creating a favorable gradient for potassium secretion. Nevertheless, ion exchange resins are often associated with the treatment to normalize potassium levels. The amount of sodium required depends on the severity of the symptoms and is deduced from the normalization of plasma potassium concentration and plasma renin. Since PHA1A improves with age, treatment can be discontinued after a variable period of time in most patients, generally around age 18–24 months. Older children are generally asymptomatic on a normal salt intake and show a normal growth and psychomotor development, although they may evolve on the lower percentiles of the growth curve, despite adequate medical therapy [339]. Follow-up of an extended family over four generations over four decades in symptomatic and asymptomatic affected family members showed age-dependent decrease in both plasma renin activity and serum aldosterone levels over the years [340], although both plasma renin and aldosterone levels remain high in adult patients [304]. Early diagnosis in affected family members mitigates the clinical course of the disease. No adverse cardiovascular outcome was reported in adult PHA1A carriers of *NR3C2* mutations, who rather show an improved diastolic left ventricular function [304].

Despite extremely elevated serum aldosterone levels during pregnancy, a recent study suggests that pregnant women may not experience ill effects [340], although careful follow-up is recommended. A higher frequency of miscarriage has been reported in women carrying *NR3C2* mutations [304].

In contrast to PHA1A, generalized PHA1B represents a therapeutic challenge. No evidence-based treatment has been described, and therapeutic intervention is patient-specific. Generally, high doses of sodium (between 20 and 50 mEq/kg/d) are used, together with ion exchange resins and dietary manipulations to reduce potassium levels. Corticoid treatment is sometimes associated and seems to provide some additional benefit. Administration of indomethacin may be useful in occasional patients [341]. Symptomatic treatment is necessary for the respiratory tract illnesses and to correct the skin phenotype. Only few cases of generalized PHA1B followed up for several years or into adulthood have been described: lifelong treatment is necessary, consisting of salt supplementation (8–20 g NaCl/day) and ion exchange resins [310, 334]. A recent study has suggested that dietary potassium restriction may be useful to attenuate urinary sodium wasting in PHA1B, although this result warrants confirmation [341].

Abstract

Magnesium (Mg^{2+}) depletion usually occurs secondary to another disease process or to a therapeutic agent. During infancy and childhood, a substantial proportion of patients receiving medical attention for signs of hypomagnesemia is affected by inherited renal disorders associated with Mg^{2+} wasting. In these disorders, hypomagnesemia either may be a leading symptom or may be part of a complex phenotype resulting from tubular dysfunction, as detailed below. Advances in molecular genetics of hereditary hypomagnesemia

Introduction/Physiology

Magnesium (Mg^{2+}) is an important intracellular cation. As a cofactor, it is involved in energy metabolism and protein and nucleic acid synthesis. It is also critical for the modulation of membrane transporters and in signal transduction. Under physiologic conditions, serum Mg^{2+} levels are maintained at almost constant values. Mg^{2+} homeostasis depends on a balanced intestinal absorption and renal excretion. Mg^{2+} deficiency can result from reduced dietary intake, intestinal malabsorption, or renal loss. The control of body Mg^{2+} homeostasis primarily resides in the kidney tubules.

The dietary intake of Mg^{2+} may vary substantially. The principal site of Mg^{2+} absorption is the small intestine, where Mg^{2+} absorption occurs via two different pathways: a saturable active transcellular transport and a nonsaturable paracellular passive transport [1, 2]. In the kidney, approximately 80% of total serum Mg^{2+} is filtered in the glomeruli, of which more than 95% is reabsorbed along the nephron. Tubular Mg^{2+} reabsorption differs in quantity and kinetics depending on the different nephron segments. In adults, approximately 15–20% is reabsorbed in the proximal tubule, whereas the premature kidney of the newborn is able to reabsorb up to 70% of the filtered Mg^{2+} in this nephron segment [3]. From early childhood on, roughly 70% of Mg^{2+} is reabsorbed in the cortical thick ascending limb (TAL) of the loop of Henle. Transport in this segment is passive and paracellular, mediated by claudin-16 and claudin-19. The driving force for reabsorption against an unfavorable concentration gradient is the lumen-positive transepithelial voltage (Fig. 1a). Only 5–10% of the filtered Mg^{2+} is reabsorbed in the distal convoluted tubule (DCT). However, in this part of the nephron the fine adjustment of renal excretion is accomplished. In the DCT, Mg^{2+} transport is an active transcellular process (Fig. 1b). Apical entry is mediated by the specific and regulated Mg^{2+} channel TRPM6. The mechanism of basolateral transport into the interstitium is unknown. Here, Mg^{2+} has to be extruded against an unfavorable electrochemical gradient. Most physiologic studies favor a Na^+-dependent exchange mechanism [4]. Mg^{2+} entry into DCT cells appears to be the rate-limiting step and the site of regulation. In the collecting duct, there is no significant Mg^{2+} uptake. Finally, 3–5% of the filtered Mg^{2+} is excreted in the urine.

Advances in molecular genetics of hereditary hypomagnesemia substantiated the role of a variety of genes and their encoded proteins in human epithelial Mg^{2+} transport, and helped to characterize different clinical subtypes of hereditary Mg^{2+}-wasting (Table 1). A careful clinical and biochemical assessment allows to distinguish the different disease entities in most cases, even when there is a considerable overlap in the phenotypic characteristics (Table 2).

Familial Hypomagnesemia with Hypercalciuria and Nephrocalcinosis

Familial hypomagnesemia with hypercalciuria and nephrocalcinosis (FHHNC) is an autosomal recessive disorder caused by mutations in two different members of the claudin gene family, namely, claudin-16 and claudin-19 [5, 6]. Since its first description, more than 150 patients have been reported allowing a comprehensive characterization of the clinical spectrum [7–17]. As a consequence of excessive renal Mg^{2+} and Ca^{2+} wasting, patients develop the characteristic triad of hypomagnesemia, hypercalciuria, and

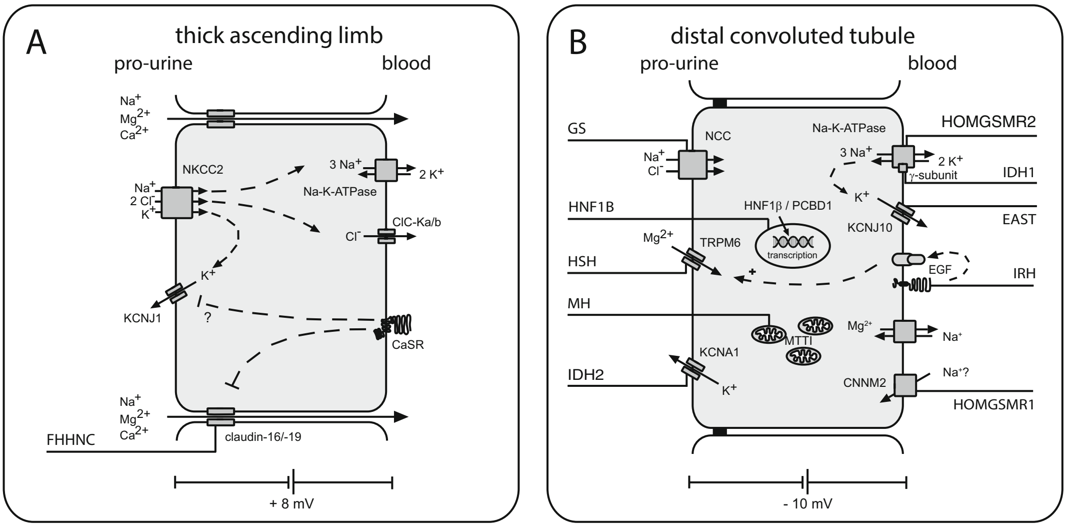

Fig. 1 Inherited disorders of magnesium reabsorption in the loop of Henle and distal convoluted tubule. (**a**) In the thick ascending limb of Henle's loop, Mg^{2+} is reabsorbed through a paracellular pathway, driven by the lumen-positive transcellular voltage generated by the transcellular reabsorption of NaCl. Mutations in the *CLDN16* and *CLDN19* genes that encode the tight junction proteins, claudin-16 and claudin-19 cause familial hypomagnesemia with hypercalciuria and nephrocalcinosis (FHHNC). (**b**) In the distal convoluted tubule, Mg^{2+} is actively reabsorbed via the transcellular pathway involving an apical entry step through a Mg^{2+}-permeable ion channel (TRPM6) and a basolateral exit, presumably mediated by a Na^+–coupled exchange mechanism. The molecular identity of the basolateral exchange is unknown. Basolateral EGF stimulates the basolateral EGF receptor EGFR, which then increases the activity of TRPM6. Mutations of *SLC12A3* coding for NCC are responsible for Gitelman syndrome (GS). Defects in the basolateral potassium channel KCNJ10 result in EAST syndrome. Mutations in the gamma-subunit of the Na^+-K^+-ATPase (*FXYD2*) cause isolated dominant hypomagnesemia (IDH1) whereas defects in KCNA1 underlie IDH2. Isolated recessive hypomagnesemia (IRH) is caused by mutations in the *EGF* gene coding for the epidermal growth factor EGF. Mutations in the apical TRPM6 channel (*TRPM6*) cause hypomagnesemia with secondary hypocalcemia (HSH). Mutations in either the α1-subunit of the Na^+-K^+-ATPase (*ATP1A1*) or CNNM2 result in hypomagnesemia, seizures, and mental retardation (HOMGSMR1 and 2). Mitochondrial hypomagnesemia (MH) is caused by a mutation in *MTTI*

nephrocalcinosis. Additional laboratory findings include elevated PTH levels before the onset of chronic kidney disease (CKD), incomplete distal tubular acidosis, hypocitraturia, and hyperuricemia, which are present in most patients [13]. Typically, FHHNC patients clinically present during early childhood with recurrent urinary tract infections, polyuria/polydipsia, nephrolithiasis, and/or failure to thrive. Clinical signs of severe hypomagnesemia are less common. The clinical course of FHHNC is frequently complicated by the development of CKD during the first two decades of life. A considerable number of patients exhibit a marked impairment of GFR (<60 ml/min/1.73 m^2) already at the time of diagnosis and about one third of patients develops ESKD during adolescence. Due to a reduction in filtered Mg^{2+} that limits urinary Mg^{2+} losses, hypomagnesemia may completely disappear with progressive decline of GFR.

Whereas the renal phenotype is almost identical in carriers of *CLDN16* and *CLDN19* mutations, severe ocular involvement is only observed in patients with *CLDN19* mutations [6, 11, 15, 16].

Simon et al. first identified *CLDN16* (formerly known as *PCLN1*), which is mutated in many patients with FHHNC [5]. *CLDN16* codes for claudin-16, a member of the claudin family. Claudins are important components of tight junctions. The individual composition of tight junctions strands with different claudin members confers the characteristic properties of different epithelia regarding paracellular permeability

and/or transepithelial resistance. In this context, a crucial role has been attributed to the first extracellular domain of the claudin protein, which is extremely variable in number and position of charged amino acid residues. Individual charges have been shown to influence paracellular ion selectivity, suggesting that claudins positioned on opposing cells forming the paracellular pathway provide charge-selective pores within the tight junction barrier.

Most mutations in *CLDN16* reported so far in FHHNC are simple missense mutations affecting the transmembrane domains and the extracellular loops with a particular clustering in the first extracellular loop. Within this domain, patients originating from Germany or Eastern European countries exhibit a common *CLDN16* mutation (L151F) due to a founder effect [13].

In FHHNC patients, progressive kidney failure is generally thought to be a consequence of massive urinary Ca^{2+} wasting and nephrocalcinosis. On the other hand, a study of a large cohort of FHHNC patients showed that the presence of *CLDN16* mutations leading to a complete loss-of-function on both alleles display a younger age at manifestation as well as a more rapid decline in kidney function compared to patients with at least one allele with residual claudin-16 function [14]. These findings support the idea that a complete lack of claudin-16 is associated with a more severe phenotype whereas a residual function delays the progression of kidney failure.

Two independent studies described a high incidence of hypercalciuria, nephrolithiasis, and/ or nephrocalcinosis in first-degree relatives of FHHNC patients [11, 13]. A subsequent study also reported a tendency toward mild hypomagnesemia in family members with heterozygous *CLDN16* mutations [18]. Thus, one might speculate that *CLDN16* mutations could be involved in the pathogenesis of idiopathic hypercalciuric stone formation.

Table 2 Clinical and biochemical characteristics of inherited disorders of renal magnesium handling

Disorder	Age at onset	Serum Mg^{2+}	Serum Ca^{2+}	Serum K^{+}	Blood pH	Urine Mg^{2+}	Urine Ca^{2+}	Nephro-calcinosis	Renal stones
Familial hypomagnesemia with hypercalciuria/nephrocalcinosis	Childhood	↓	N	N	N or ↓	↑↑	↑↑	yes	yes
Gitelman syndrome	Adolescence	↓	N	↓	↑	↑	↓	no	no
EAST/SeSAME syndrome	Infancy	↓	N	↓	↑	↑	↓	no	no
Isolated	Childhood	↓	N	N	N	↑	↓	no	no
Isolated recessive hypomagnesemia	Childhood	↓	N	N	N	↑	N	no	no
Hypomagnesemia, seizures, mental retardation 1	Infancy to adolescence	↓↓↓	↓	N	N	↑	N	no	no
Hypomagnesemia, seizures, mental retardation 2	Infancy	↓↓↓	N	N or ↓	N	↑↑	N	no	no
HNF1B nephropathy	Broad range	↓	N	N	N	↑	↓	no	no
Hypomagnesemia after transient neonatal hyperphenylalaninemia	Adulthood	↓	N	N	↑	↑	N	no	no
Hypomagnesemia/metabolic syndrome	Adulthood	↓	N	N	N	↑	↓	no	no

A homozygous *CLDN16* mutation (T303R) affecting the C-terminal PDZ domain has been identified in two families with isolated hypercalciuria and nephrocalcinosis without disturbances in renal Mg^{2+} handling [19]. Interestingly, the hypercalciuria disappeared during follow-up and urinary Ca^{2+} levels reached normal values beyond puberty.

Molecular genetic studies in FHHNC patients with severe ocular involvement lead to the identification of mutations in a second member of the claudin family, namely, claudin-19 (encoded by *CLDN19*) [14]. The identification of *CLDN19* mutations could explain the variable ocular phenotype observed in FHHNC, because *CLDN19* defects seem to be invariably associated with severe ocular abnormalities (including severe myopia, nystagmus, or macular coloboma) [10–12]. The latter association has been named FHHNC with severe ocular involvement. In contrast, only a small subset of FHHNC patients with *CLDN16* defects displays severe myopia whereas nystagmus or colobomata have not been described [13]. The renal phenotype is very similar between these two FHHNC subtypes. Expression studies revealed that claudin-16 and claudin-19 perfectly colocalize at tight junctions of the TAL [6]. It could further be demonstrated that claudin-16 and claudin-19 functionally interact, which could increase the cation selectivity of tight junctions above that of claudin-16 alone [20]. This is most likely due to anion-blocking properties of claudin-19 preventing back diffusion of Cl^{-} anions to the tubular lumen.

Besides continuous oral Mg^{2+} supplementation, the therapy aims to reduce Ca^{2+} excretion in order to prevent the progression of nephrocalcinosis and stone formation because the degree of renal calcifications has been correlated with progression of CKD [11]. In a short-term study, thiazides have been demonstrated to effectively reduce urinary Ca^{2+} excretion in FHHNC patients [21]. However, these therapeutic strategies have not been shown yet to significantly influence the progression of CKD. Supportive therapy is important for the protection of kidney function and should include provision of sufficient fluids and effective treatment of stone formation and bacterial colonization. Kidney transplantation does not result in recurrence of the disease because the primary defect resides in the kidney.

Gitelman Syndrome

This primary salt-wasting disorder complicated by urinary Mg^{2+} wasting and hypomagnesemia is discussed in detail in ▶ Chap. 41, "Inherited Disorders of Sodium and Potassium Handling." With respect to hypomagnesemia, it is important to emphasize that hypomagnesemia is typical for Gitelman syndrome (GS) but not a universal finding, especially in young patients.

EAST/SeSAME Syndrome

In 2009, a new disease entity with autosomal recessive inheritance combining epilepsy, ataxia, sensorineural deafness, and renal NaCl wasting with/without mental retardation was described under the acronyms EAST or SeSAME syndrome [22, 23]. Patients usually present early in infancy with seizures, developmental delay, and ataxia. In addition, they exhibit a severe hearing impairment. Renal salt wasting may develop or be recognized only later during the course of the disease [24]. Closely resembling GS, the renal phenotype includes the combination of hypokalemic alkalosis, hypomagnesemia, and hypocalciuria.

EAST/SeSAME syndrome is caused by loss of function mutations in the *KCNJ10* gene encoding the inwardly rectifying K^{+}-channel KCNJ10 (Kir4.1) [22, 23]. The expression pattern of KCNJ10 fits to the disease phenotype with high expression levels in brain, the stria vascularis of the inner ear, and in the distal nephron, especially in the DCT. Here, KCNJ10 is localized at the basolateral membrane of DCT cells (Fig. 1b) and supposed to function in collaboration with Na^{+}-K^{+}-ATPase as it might allow for a recycling of K^{+} ions entering the tubular cells in a countermove for the extruded Na^{+} [23]. Loss of KCNJ10 function most likely leads to a depolarization of the basolateral membrane and thereby to a reduction of the driving force for basolateral anion channels as well as sodium-coupled exchangers. By this mechanism, KCNJ10 defects could also affect the putative Na^+/Mg^{2+} exchanger and possibly explain the Mg^{2+} wasting observed in EAST/SeSAME syndrome. Moreover, it could be demonstrated that lack of KCNJ10 decreases basolateral Cl^- conductance and results is a diminished expression of NCC in the apical membrane [25]. These results could explain the salt loss observed in EAST/SeSAME patients.

Isolated Dominant Hypomagnesemia 1

A first variant of isolated dominant hypomagnesemia (IDH1, OMIM #154020) was described in two related families by Meij et al. who discovered a missense mutation in the *FXYD2* gene, which encodes a γ-subunit of the Na^+K^+-ATPase [26]. The index patients presented with seizures during childhood (at 7 and 13 years) with serum Mg^{2+} levels of approximately 0.4 mmol/L. One patient was treated for seizures of unknown origin with antiepileptic drugs until serum Mg^{2+} levels were evaluated during adolescence. At that time mental retardation was evident [27, 28]. Serum Mg^{2+} measurements performed in additional members of both families revealed low serum Mg^{2+} levels in numerous apparently healthy individuals. Urinary Mg^{2+} measurements in affected family members revealed significant renal Mg^{2+} loss (around 5 mmol per day) despite profound hypomagnesemia. Instead, the intestinal absorption of Mg^{2+} was preserved and even stimulated in compensation for the increased renal losses. Urinary Ca^{2+} excretion rates were low in all hypomagnesemic individuals, a finding reminiscent of patients presenting with GS. In two additional families described with the same mutation, careful biochemical workup revealed a tendency toward hypokalemia and metabolic alkalosis. Muscle cramps, seizures, and chondrocalcinosis were frequent clinical findings [29].

The protein encoded by *FXYD2* is a member of a small single transmembrane protein family, which share the common amino acid motif F-X-Y-D. FXYD proteins modulate the function of the ubiquitous Na^+-K^+-ATPase, a dimeric enzyme invariably consisting of one α- and one β-subunit (Fig. 1). FXYD proteins constitute a third or γ-subunit that represents a tissue-specific regulator of the Na^+-K^+-ATPase. FXYD2 is expressed in the distal nephron, especially in the DCT and connecting tubule [30]. The FXYD2 γ-subunit increases the apparent affinity of Na^+-K^+-ATPase for ATP while decreasing its Na^+ affinity [31]. Thus, it might provide a mechanism for balancing energy utilization and maintaining appropriate salt gradients.

Expression studies of the mutant G41R-γ-subunit revealed a dominant-negative effect leading to a retention of the γ-subunit in the Golgi complex. The mechanism of a dominant negative effect is supported by the observation that individuals with a large heterozygous deletion of chromosome 11q including the *FXYD2* gene exhibit normal serum Mg^{2+} levels [32]. Urinary Mg^{2+} wasting together with the expression pattern of the *FXYD2* gene indicate defective transcellular Mg^{2+} reabsorption in the DCT. The exact mechanism causing increased urinary Mg^{2+} excretion is yet to be determined.

Isolated Dominant Hypomagnesemia 2

Genetic heterogeneity in IDH was demonstrated by the identification of a heterozygous missense mutation in the *KCNA1* gene, which encodes the voltage-gated potassium channel KCNA1 (Kv1.1) [33]. The observed clinical picture includes early onset muscle cramps, tetany, tremor, and muscle weakness. Biochemical workup revealed a renal Mg^{2+} leak without alterations in renal Ca^{2+} handling. Mutations in *KCNA1* had previously been identified in patients with episodic ataxia with myokymia (OMIM 160120), a neurologic disorder characterized by an intermittent appearance of incoordination and imbalance as well as myokymia, an involuntary, spontaneous, and localized trembling of muscles. In addition to muscle cramps and tetany attributed to Mg^{2+} deficiency, these symptoms were also present in members of the aforementioned family with hypomagnesemia.

The mutation in *KCNA1* described in hypomagnesemic patients leads to a nonconservative amino acid exchange (N255D) in KCNA1. Functional voltage-gated K^+-channels of the KCNA family are composed of tetramers. Coexpression of the N255D mutant with wild-type KCNA1 subunits revealed a dominant negative effect that rather seems to result from impaired channel gating since trafficking to the plasma membrane is preserved [34].

KCNA1 expression was demonstrated in DCT cells at the apical membrane (Fig. 1b). Because of its colocalization with TRPM6, a model was proposed in which KCNA1 allows for hyperpolarization of the apical membrane of DCT cells as a prerequisite for TRPM6-mediated Mg^{2+} entry (Fig. 1b).

Isolated Recessive Hypomagnesemia

Geven and colleagues reported a form of isolated recessive hypomagnesemia (IRH) in a consanguineous family [35]. Two affected girls presented with generalized seizures during infancy. Possibly related to late diagnosis, both patients also exhibited neurodevelopmental deficits. Clinical and laboratory workup at 4 and 8 years of age, respectively, revealed serum Mg^{2+} levels around 0.5–0.6 mmol/L with no other associated electrolyte abnormalities. Both patients exhibited renal Mg^{2+} excretion of 3–6 mmol per day despite hypomagnesemia confirming renal Mg^{2+} wasting. Renal Ca^{2+} excretion rates in IRH are within the normal range.

As the underlying molecular defect, a homozygous P1070L mutation in the *EGF* gene encoding the epidermal growth factor EGF was identified [36]. The EGF protein is expressed in the DCT, and its binding to the receptor EGFR is essential for the function of the TRPM6 channel (Fig. 1b). The mutation is located in the cytosolic C-terminal terminus within a sorting motif (PXXP), which is necessary for the trafficking of EGF to the basolateral membrane. Expression studies demonstrated that mutant pro-EGF retains EGF secretion to the apical membrane but does not reach the EGF receptor in the basolateral membrane, resulting in dysfunction of TRPM6 [36]. Even if IRH seems to be an extremely rare disease phenotype, the identification of EGF mutations is important because this is the first autocrine/paracrine magnesiotropic hormone known at the molecular level.

Hypomagnesemia with Secondary Hypocalcemia

Hypomagnesemia with secondary hypocalcemia (HSH) is a rare recessive disorder that presents in early infancy with generalized seizures or other clinical signs of increased neuromuscular excitability [37]. Biochemical abnormalities include extremely low serum Mg^{2+} (about 0.2 mmol/L) and low serum Ca^{2+} levels. Hypocalcemia is thought to result from an impaired synthesis and/or release of PTH in the presence of severe hypomagnesemia [38]. The mechanism leading to hypocalcemia is not completely clear, but severe hypomagnesemia results in impaired synthesis and/or release of PTH [39]. The hypocalcemia observed in HSH does not respond to therapy with Ca^{2+} or vitamin D. Relief of clinical symptoms, normocalcemia, and normalization of PTH levels are only achieved by administration of high doses of Mg^{2+} [40]. Serum magnesium levels usually remain in the subnormal range despite adequate treatment but enable an undisturbed physical and mental development in most patients. However, delayed diagnosis or noncompliance with treatment can be fatal or result in permanent neurological damage.

Transport studies in HSH patients pointed to a primary defect in intestinal Mg^{2+} absorption [41, 42]. However, in some patients an additional renal leak for Mg^{2+} was suspected [43].

In 2002, recessive loss of function mutations in TRPM6 encoding a member of the transient receptor potential (TRP) family of ion channels was discovered as the underlying genetic defect [44, 45]. To date, mutations in *TRPM6* have been identified in more than 50 families affected by HSH [44–48]. The mutational spectrum mainly comprises truncating mutations. In addition, a number of missense mutations have been described for which functional analyses also indicated a complete loss-of-function [44, 46, 48, 49].

TRPM6 encodes a member of the transient receptor potential (TRP) family of cation ion channels. It is expressed along the intestine as well as in the DCT of the kidney [44]. In the intestine, intraluminal Mg^{2+} concentrations and rates of Mg^{2+} absorption show a curvilinear relationship presumably reflecting two transport processes working in parallel: an active and saturable transcellular transport essential at low intraluminal Mg^{2+} concentrations and a passive paracellular Mg^{2+} absorption gaining importance at higher intraluminal Mg^{2+} concentrations [1]. The observation that in HSH patients the substitution of high oral doses of Mg^{2+} achieves at least subnormal serum Mg^{2+} levels supports the idea of two independent intestinal transport systems for Mg^{2+}. TRPM6 probably represents a molecular component of active transcellular Mg^{2+} transport. An increased intraluminal Mg^{2+} concentration (by increased oral intake) enables to compensate for the defect in active transcellular transport by increasing absorption via the passive paracellular pathway.

The detection of TRPM6 expression in the DCT confirmed the hypothesis of an additional role of renal Mg^{2+} wasting for the pathogenesis of HSH [50]. This was also supported by intravenous Mg^{2+} loading tests in HSH patients, which disclosed a considerable renal Mg^{2+} leak albeit still being hypomagnesemic [45].

TRPM6 is thought to participate in the formation of magnesium-permeable ion channels in the apical membrane of DCT cells (Fig. 1b). As electrophysiological experiments yielded controversial data, it is still unclear if TRPM6 constitutes homomeric ion channels in vivo or is involved in the formation of heterotetramers with its close homologue TRPM7 [51–53].

Hypomagnesemia, Refractory Seizures, and Mental Retardation 1

Another form of hereditary Mg^{2+} wasting could be linked to mutations in *CNNM2* encoding the transmembrane protein CNNM2 or Cyclin M2 [54].

Stuiver et al. identified heterozygous CNNM2 mutations in two families with dominant hypomagnesemia [54]. Clinical symptoms and age at manifestation were variable with symptoms ranging from seizures in early childhood to muscle weakness, vertigo, and headache during adolescence. Other heterozygous carriers from both families even remained asymptomatic. Except for hypomagnesemia (Mg^{2+} of 0.36 to 0.51 mmol/L in symptomatic patients), no additional biochemical abnormalities were reported. Whereas a truncating frame-shift mutation was identified in one of the described families, affected individuals of the second family were found to carry a missense mutation leading to a nonconservative amino acid exchange in CNNM2 [54]. Patch clamp analyses revealed a significant reduction in Mg^{2+}-sensitive, inwardly rectifying Na^{+} currents for this missense mutant [54].

The phenotypic and genetic spectrum of CNNM2-associated disease was broadened by the identification of a recessive mutation in a family with parental consanguinity [55]. The two affected siblings exhibited hypomagnesemia (~0.5 mmol/L) and a severe degree of psychomotor retardation. Magnetic resonance imaging of the central nervous system in one of the patients revealed widened outer cerebrospinal liquor spaces as well as myelinization defects. The finding of a severe neurological phenotype caused by bi-allelic *CNNM2* mutations was substantiated by a second study describing a second homozygous mutation in *CNNM2* in a patient with a similar clinical picture comprising refractory epilepsy, microcephaly, global developmental delay, and intellectual disability [56]. Later, the description of a larger cohort of patients enabled a more detailed clinical description of the phenotype associated with heterozygous CNNM2 defects [57]. Serum Mg^{2+} levels are typically in the range of 0.5–0.6 mmol/L, insufficiently respond to oral Mg^{2+} supplementation, and remain in the subnormal range. Patients typically manifest with cerebral seizures in infancy, but seizures subside during follow-up in most patients. However, patients uniformly show a mild to moderate degree of neurodevelopmental delay with a disturbed speech development and dysarthria as prominent features. Finally, a considerable number of patients of both genders develops obesity (BMI >97th percentile) as the most prominent extraneurological symptom [57].

The precise physiological function of CNNM2 still remains enigmatic. CNNM2 is ubiquitously expressed in mammalian tissues, most prominently in kidney, brain, and lung [58, 59]. In the kidney, CNNM2 expression was demonstrated at the basolateral membrane of TAL and DCT.

Although CNNM2 had been proposed as a Mg^{2+}-transporter after overexpression studies in *Xenopus* oocytes [60], Mg^{2+}-transport could not be directly measured in mammalian cells using patch clamp analyses [54]. In-silico modeling of CNNM2 protein domains identified a Mg^{2+}-ATP-binding site suggesting a putative role in Mg^{2+} sensing [59]. Using stable Mg^{2+}-isotopes, an increase in cellular Mg^{2+}-uptake could be demonstrated after overexpression of CNNM2, an effect that was abrogated by the introduction of pathogenic mutations identified in hypomagnesemic patients [55, 57]. Finally, CNNM2 function was studied in the zebrafish model. Here, knockdown of CNNM2 expression leads to a decrease in whole-body Mg^{2+} as well as developmental defects of the central nervous system in line with human disease [55]. Further studies will be needed to clarify if CNNM2 serves as a Mg^{2+}-sensor or if it by itself is able to transport Mg^{2+}.

Hypomagnesemia, Refractory Seizures, and Mental Retardation 2

Heterozygous de novo mutations in *ATP1A1* encoding the α1-subunit of Na^+K^+-ATPase have recently been described in three children with severe hypomagnesemia due to renal Mg^{2+} wasting [61]. Affected individuals presented during infancy with seizures that were not responsive to antiepileptic medication and did not cessate upon Mg^{2+} supplementation. All three children developed a significant degree of mental retardation and global developmental delay. Of note, serum Mg^{2+} concentrations remained low despite adequate supplementation.

The α1-subunit (ATP1A1) is one of four different α-subunits of Na^+K^+-ATPase in human, but it represents the exclusive α-subunit in kidney. Along the kidney tubule, the DCT represents the segment with the highest energy consumption and density of Na^+K^+-ATPase expression [62]. Here, basolaterally expressed Na^+K^+-ATPase generates favorable electrochemical gradients for transcellular NaCl and Mg^{2+} reabsorption. The critical role of Na^+K^+-ATPase for Mg^{2+} reabsorption had previously been demonstrated by discovery of mutations in its γ-subunit (*FXYD2*) in patients with isolated dominant hypomagnesemia (see above). In the central nervous system, the α1-subunit is ubiquitously expressed and thought to maintain neuronal housekeeping functions [63].

The ATP1A1 mutations discovered in hypomagnesemic children were shown to not only lead to a loss of ATPase function, but also to result in abnormal ion permeabilities and leak currents [61]. Therefore, the severe hypomagnesemia phenotype might not be the result of a simple ATP1A1 haploinsufficiency. Whereas a homozygous loss of ATP1A1 function is not compatible with life, heterozygous germline ATP1A1 mutations have also been described in patients with Charcot-Marie-Tooth disease type 2 and hereditary spastic paraplegia [64, 65].

HNF1B Nephropathy

Hepatocyte nuclear factor 1β (HNF1B) is a transcription factor, which plays a critical role in the development of the kidney and the pancreas. Heterozygous mutations in *HNF1B* were initially reported in maturity-onset diabetes of the young (MODY5) [66]. *HNF1B* mutations occur in the heterozygous state, either inherited or de novo, and comprise point mutations as well as whole gene deletions [67]. Subsequent reports described an association with developmental kidney disease. The kidney anomalies are highly variable comprising enlarged hyperechogenic kidneys, multicystic kidney disease, renal agenesis, renal hypoplasia, cystic dysplasia, as well as hyperuricemic nephropathy. The association of MODY and cystic kidneys led to the term renal cysts and diabetes syndrome (RCAD) [68]. However, this denomination might be misleading because neither the renal cystic phenotype nor the diabetes is a constant clinical finding [69]. For this reason, the new term HNF1B nephropathy has been introduced.

Approximately 50% of patients develop hypomagnesemia due to impaired renal Mg^{2+} reabsorption [70]. Renal Mg^{2+} wasting is accompanied by hypocalciuria indicating an involvement of the DCT [70]. A follow-up study investigated the tubulopathy associated with HNF1B nephropathy in more detail and also demonstrated hypokalemia and metabolic alkalosis in addition to hypomagnesemia and hypocalciuria pointing to a general disturbance of the DCT [71]. As another study identified hypomagnesemia only in a smaller percentage of affected children (25%), it was shown that this phenotypic feature of HNF1B nephropathy represents an age-dependent phenomenon and develops over time [72]. This assumption was supported by a Polish study that reported an increasing fraction of hypomagnesemic HNF1B patients during follow-up [73].

Transient Neonatal Hyperphenylalaninemia

Renal Mg^{2+} wasting has recently been described in transient neonatal hyperphenylalaninemia due to recessive mutations in the *PCBD1* gene [74]. Affected individuals were shown to develop hypomagnesemia and a MODY type diabetes at adult age. Functional studies revealed that PCBD1 is an essential dimerization cofactor of HNF1B. It was demonstrated that a defective dimerization of PCBD1 with HNF1B abrogated the HNF1B-mediated stimulation of *FXYD2* promoter activity in the DCT [74].

Mitochondrial Hypomagnesemia

A mutation in the mitochondrially encoded isoleucine tRNA gene, $tRNA^{Ile}$ or MTTI, related to hypomagnesemia has been discovered in a large Caucasian kindred [75]. An extensive clinical evaluation of this family was prompted after the discovery of hypomagnesemia in the index patient, leading to the characterization of mitochondrial hypomagnesemia. Indeed, pedigree analysis was compatible with mitochondrial inheritance as the phenotype was exclusively transmitted by affected females. The phenotype includes hypomagnesemia, hypercholesterolemia, and hypertension. Of the adults on the maternal lineage, the majority of offspring exhibited at least one of the mentioned symptoms, approximately half of the individuals showed a combination of two or more symptoms, and around 1/6 had all three features. Serum Mg^{2+} levels of family members on the maternal lineage varied greatly from ~0.3 to ~1.0 mmol/L with approximately 50% of individuals being hypomagnesemic. The hypomagnesemic individuals showed higher fractional excretion rates (median around 7.5%) than their normomagnesemic relatives (median around 3%) clearly pointing to renal Mg^{2+} wasting as causative for hypomagnesemia. Interestingly, hypomagnesemia was accompanied by decreased urinary Ca^{2+} levels, a finding pointing to the DCT as the affected tubular segment.

As ATP consumption along the tubule is highest in the DCT, the authors speculate about an impaired energy metabolism of DCT cells as a consequence of the mitochondrial defect, which in turn could lead to disturbed transcellular Mg^{2+} reabsorption [75]. Further studies in these patients might help to better understand the mechanism of distal tubular Mg^{2+} wasting in this disease.

Management of Hypomagnesemia/Magnesium Deficiency

The main goal of Mg^{2+} substitution in hypomagnesemic patients is the relief of clinical symptoms. In most cases, especially in primary Mg^{2+} wasting diseases, normal levels cannot be achieved by oral substitution without considerable gastrointestinal side effects. The route of administration depends on the severity of clinical symptoms. Acute intravenous infusions should be reserved for patients with severe symptoms, i.e., with cerebral seizures [76]. Especially in children, painful intramuscular injections should be avoided. In infants and children, the starting dose is 20–50 mg Mg^{2+} sulfate (0.1–0.2 mmol Mg^{2+}) per kilogram body weight. Mg^{2+} sulfate should be given slowly intravenously (over 20 min). The maximum dose for adults is 2 g of Mg^{2+} sulfate. Single doses can be repeated every 6–8 h or followed by continous infusion of 100–200 mg Mg^{2+} sulfate (0.4–0.8 mmol Mg^{2+}) per kilogram body weight per day [77]. During Mg^{2+} infusion, close monitoring of cardiorespiratory function is important and Ca^{2+} gluconate should be available as an antidote. The assessment of kidney function is also mandatory.

Asymptomatic hypomagnesemia or chronic Mg^{2+} deficiency should be treated with oral Mg^{2+} substitution. In children, 10–20 mg Mg^{2+} (0.4–0.8 mmol) per kg body weight given three to four times a day has been recommended to correct hypomagnesemia [78]. Of note, the solubility, intestinal absorption, and side effects considerably differ depending on the Mg^{2+} salt used for oral therapy. The bioavailability and pharmacokinetics of different Mg^{2+} salts have been reviewed in [79]. With respect to solubility, intestinal absorption, and bioavailability, organic Mg^{2+} salts (e.g., citrate or aspartate) appear most suitable for oral substitution. Moreover, the laxative effect of organic Mg^{2+} salts seems to be less pronounced compared to inorganic salts.

The use of certain diuretics has been proposed for the reduction of renal Mg^{2+} excretion. Both, K^+-sparing diuretics and aldosterone antagonists, exert Mg^{2+}-sparing effects [80, 81]. Their beneficial effect on renal Mg^{2+} excretion, serum Mg^{2+} levels and clinical symptoms is well documented in hereditary Mg^{2+}-wasting diseases [82].

Abstract

Human calcium homeostasis is maintained by a complex interplay of different hormonal systems controlling intestinal calcium uptake, renal calcium excretion, and calcium transport in bone and soft tissues. Changes in renal calcium handling may either reflect a renal compensation for disturbances in body calcium homeostasis or its hormonal regulation, or a primary defect in renal tubular calcium transport. Irrespective of the underlying etiology, hypercalciuria represents a major risk factor for renal calcifications and kidney stone disease requiring a thorough diagnostic workup. Especially in infants and young children, hereditary disorders of calcium metabolism and tubular calcium reabsorption have to be considered in the differential diagnosis. The elucidation of the underlying genetic etiology might directly affect the management of affected children.

Calcium Physiology

Elemental calcium constitutes around 1 kg of adult human body mass of which 99% are bound in bone. Extracellular fluid only contains approximately 1 g of calcium. In serum, around 50 % of calcium are present in the free ionized form (Ca^{2+}), ~35 % are protein-bound, and ~15 % are complexed to bicarbonate, citrate, or phosphate. The physiological range for blood calcium equals 1.1 to 1.35 mmol/L for free, ionized Ca^{2+} and 2.2 to 2.6 mmol/L for total calcium (in the presence of physiological whole protein levels) [1]. Only the free, ionized fraction is responsible for the biological calcium effects.

According to recommendations of national boards of nutrition, 1000 to 1200 mg of calcium should be taken up daily with a normal diet [2, 3]. The intestine reabsorbs approximately 25 to 33 % of the nutritional calcium content [4]. In the kidney, approximately 800 mg of ionized Ca^{2+} is filtered daily in the glomeruli of which 99 % is reabsorbed along the tubule. Only ~10 mg (~0.1mg/kg/day) is finally excreted in the urine.

Blood calcium levels are kept within a narrow physiological range by the concerted action of different hormonal systems that control intestinal calcium uptake, renal calcium excretion, and calcium transport in bone and soft tissues. These comprise the parathyroid gland with parathyroid hormone (PTH), active 1,25-$(OH)_2$-vitamin D_3, and the bone-derived, phosphaturic hormone FGF-23 [5].

All three systems are tightly linked and influence each other's activity. PTH increases intestinal calcium absorption and calcium release from bone, and it promotes renal calcium reabsorption while stimulating renal phosphate excretion. In contrast, active 1,25-$(OH)_2$-vitamin D_3 promotes intestinal calcium and phosphate absorption as well as renal calcium and phosphate conservation thereby ensuring sufficient calcium and phosphate supply for bone mineralization. Finally, FGF-23 together with its co-factor klotho increases renal phosphate excretion by inhibiting proximal tubular phosphate reabsorption [5, 6]. In addition, FGF-23 also negatively regulates vitamin D by inhibiting its activation and promoting its degradation. The common aim of this hormonal interplay is to keep extracellular calcium levels constant while supplying sufficient amounts of calcium for soft tissues and bone mineralization.

At the glomerulus, the ionized fraction of serum calcium is freely filtered. The majority of filtered calcium (60–70%) is already reabsorbed in the proximal tubule (Fig. 1) [7]. Classically, calcium transport in the proximal tubule is considered to occur via the paracellular pathway driven by active transcellular sodium reabsorption and paracellular water flow [8]. Apical uptake of sodium into the proximal tubular cell is achieved via the sodium proton exchanger NHE3 (*SLC9A3*) and followed by a basolateral extrusion via Na-K-ATPase [9]. The paracellular space in the proximal tubule has a high permeability for ions and water that is conferred by tight junctions composed of claudin-2, claudin-10, and claudin-12 [10, 11]. Interestingly, recent data also indicate transcellular calcium transport in the proximal tubule involving apically expressed Calcium-sensing receptor (CaSR) and the calcium-permeable ion channel TRPC3 (transient receptor potential family C member 3) [12].

Around 25% of filtered calcium is reabsorbed in the thick ascending limb (TAL) of the loop of Henle. Here, calcium transport is passive and paracellular in nature and occurs together with magnesium (see below). It is driven by a lumen-positive transepithelial voltage generated by active transcellular salt reabsorption. Next to changes in transcellular sodium chloride reabsorption, the permeability and cation selectivity of the paracellular pathway play a critical role in determining calcium and magnesium reabsorption. Paracellular tight junctions in the TAL are composed of a complex set of claudin proteins conferring different properties: claudin-16 and claudin-19 facilitate paracellular calcium and magnesium transport, but also influence sodium permeability while sealing the paracellular space for chloride [13]. Furthermore, paracellular movement of calcium and magnesium is modified by claudin-10 which is thought to form a paracellular sodium pore [14]. Paracellular calcium and magnesium transport in the

Fig. 1 Calcium reabsorption along the kidney tubule and inherited disorders affecting calcium metabolism and renal calcium handling (A) In the proximal tubule, calcium is reabsorbed via a paracellular pathway through tight junctions containing claudin-2. Moreover, the enzymes responsible for vitamin D activation, 1α-hydroxylase (CYP27B1), and vitamin D inactivation, 24-hydroxylase (CYP24A1), are expressed in proximal tubular cells and are functionally linked to phosphate reabsorption via NaPi-IIa (SLC34A1) and NaPi-IIc (SLC34A3). (B) In the thick ascending limb (TAL) of Henle's loop, calcium is reabsorbed together with magnesium through paracellular tight junctions composed by claudin-16 and -19. This process is negatively regulated by the basolateral Calcium-sensing receptor (CaSR) and PTH. Mutations in the CaSR and its associated proteins cause changes in calcium metabolism (see text for details). (C) In the distal convoluted tubule (DCT), calcium is actively reabsorbed via the transcellular pathway involving an apical entry through TRPV5 and a basolateral exit via Ca^{2+}-ATPase and Na^{+}-Ca^{2+}-exchanger (NCX). There are no known monogenic disorders affecting calcium reabsorption in the DCT

TAL is regulated by a complex network involving claudin-14 as well as the CaSR and PTH receptor, both expressed at the basolateral membrane [15–17]. Claudin-14 interacts with claudin-16 and diminishes paracellular cation permeability *in vitro*. Under physiologic conditions, the expression of claudin-14 is suppressed via a microRNA pathway [18]. By activation of the CaSR, extracellular calcium is able to relieve this suppression, induce claudin-14 expression, and inhibit paracellular divalent cation reabsorption [16]. The CaSR is a guanine nucleotide-binding protein (G-protein)-coupled receptor that stimulates phospholipase C through G-proteins G_q and G_{11} resulting in the production of inositol 1,4,5-trisphosphate. This in turn leads to a reduction in PTH secretion from the parathyroid gland as well as increased urinary calcium and magnesium excretions [19]. Finally, claudin-14 expression and therefore paracellular cation transport are directly regulated by PTH via basolaterally expressed PTH-receptor PTH1R [17].

The distal convoluted tubule (DCT) only reabsorbs a small proportion of filtered calcium (10 - 15 %); however, as for magnesium, the DCT determines the final urinary excretion as there is no calcium reabsorption beyond this segment. Transcellular calcium reabsorption in the DCT is a sequential process of three steps: apical entry into the epithelial cell through calcium-permeable ion channels (TRPV5), binding to calbindin-D_{28k} for diffusion through the cytoplasm, and basolateral exit through either a Ca^{2+}-ATPase (PMCA1b, *ATP2B1*), or a Na^{+}-Ca^{2+}-exchanger (NCX1, *SLC8A1*) [20]. Transcellular calcium reabsorption in the DCT is critically influenced by PTH and active 1,25-OH_2-vit D_3 that regulate the expression levels of all of these transcellular transport proteins [21]. In addition, calcium (as well as magnesium) handling in the DCT appears to depend on dietary potassium and the rate of active transcellular salt reabsorption [22, 23].

Disturbances of Calcium Homeostasis

Disturbances in calcium metabolism comprise states of calcium deficiency as well as calcium excess usually detected in the form of hypo- or hypercalcemia. Whereas hypocalcemia represents a more common finding and is usually apparent by typical clinical signs and symptoms, hypercalcemia in infancy and childhood is a rare event and may remain unrecognized as clinical symptoms are rather unspecific. Here, we focus on hereditary disorders of calcium metabolism. These typically manifest with characteristic changes in serum and urine calcium levels. As for acquired disorders of calcium homeostasis, the diagnostic work-up, next to the parallel measurement of serum and urine electrolytes and creatinine, comprises the determination of parathyroid hormone (PTH) and vitamin D metabolites.

Hypercalciuria

An increased urinary calcium excretion may disclose [1] an appropriate renal response to excessive amounts of calcium from circulation and [2] an inappropriate renal Ca^{2+} conservation with or without apparent changes in body calcium homeostasis and in its hormonal regulation. The assessment of urinary calcium excretion is commonly performed by either 24h urine collections and calculation of daily calcium excretion per kg body weight or by calculation of the calcium/creatinine ratio from spot urine samples. For reference values for renal calcium excretion in infants and children, please refer to Matos et al. [24].

Hypercalciuria is the most common risk factor for nephrocalcinosis and kidney stone formation in children [25]. The etiology is assumed to be multifactorial with a complex interaction of environmental and genetic factors. Still, despite an increased knowledge in the underlying genetic causes, the majority of patients are classified as having idiopathic hypercalciuria. A detailed overview on hypercalciuria and its role in the etiology of nephrocalcinosis and kidney stone disease is also provided in chapter “Urolithiasis and Nephrocalcinosis”.

In the past two decades, genetic studies have been able to identify variants in an increasing number of genes and proteins involved in tubular calcium reabsorption in patients with hypercalciuria, nephrocalcinosis and kidney stone disease. Classic examples of a primary disturbance of renal tubular calcium (and magnesium) reabsorption are hereditary defects in the two tight junction proteins claudin-16 and -19 in patients with familial hypomagnesemia with hypercalciuria and nephrocalcinosis (FHHNC) (HOMG3, OMIM #248250; HOMG5, OMIM #248190) as well as activating and deactivating mutations in the CaSR producing mirror images of disturbed calcium homeostasis

(ADH1, OMIM #601198; FHH1, OMIM #144980; NSHPT, OMIM #239200). Whereas FHHNC is discussed in detail in chapter on “inherited disorders of renal magnesium handling”, the hereditary defects of CaSR function are presented below in the respective paragraphs on hypo- and hypercalcemia.

Established disorders associated with hypercalciuria and nephrocalcinosis affecting proximal tubular calcium reabsorption comprise different forms of hereditary renal Fanconi syndrome (FRTS1 (GATM), OMIM 134600; FRTS3 (EHHADH), OMIM 615605; FRTS4 (HNF4A), OMIM 616026), Dent’s disease (DENT1, OMIM #300009; DENT2, OMIM #300555), Lowe syndrome (OMIM #309000), nephropathic cystinosis (CTNS, OMIM 219800), Fanconi Bickel syndrome (FBS, OMIM 227810), Tyrosinemia (TYRSN1, OMIM 276700), Galactosemia (GALAC1, OMIM 230400), as well as primary mitochondrial disorders [26]. These disorders are discussed in more detail elsewhere.

As paracellular calcium and magnesium reabsorption in the TAL depends on transepithelial voltage generated by active transcellular salt reabsorption, different types of Bartter syndrome affecting salt reabsorption in the TAL typically lead to hypercalciuria and nephrocalcinosis (Table 1) (see chapter “Inherited disorders of sodium and potassium handling”).

Finally, hypercalciuria and nephrocalcinosis are commonly observed in patients with different forms of distal renal tubular acidosis (RTA). Hypercalciuria in dRTA is typically believed to result from an increased release of calcium from bone; however, metabolic acidosis also directly affects renal tubular calcium handling. The effects of changes in systemic acid-base status on paracellular transport processes in the proximal tubule and TAL have not been fully elucidated. An increased serum load of bone-derived calcium could theoretically inhibits tubular calcium reabsorption via the CaSR and increases claudin-14 expression in paracellular tight junctions in the TAL [27]. Moreover, metabolic acidosis has been shown to directly downregulate the expression of calcium (and magnesium) transport proteins in the DCT [28]. The different forms of renal tubular acidosis are presented in ▶ Chap. 38, “Renal Tubular Acidosis”.

An overview of hereditary disorders leading to an increased urinary excretion of calcium, nephrocalcinosis, and kidney stone disease is provided in Table 1.

A recent study directly implicates defective paracellular calcium reabsorption in the proximal tubule in the pathogenesis of hypercalciuria and renal calcifications as deletion of claudin-2 in mice was shown to result in hypercalciuria and renal calcifications [29]. The same study also identified a potentially pathogenic heterozygous variant in *CLDN2* in a family with multiple members affected by kidney stones and associated common genetic variants near the *CLDN2* locus with kidney stone risk [29].

Surprisingly and in contrast to calcium and magnesium reabsorption in the TAL as well as magnesium reabsorption in the DCT (see below), a primary defect in transcellular calcium reabsorption in the DCT could not yet be linked to monogenic human disease. Deletion of the epithelial calcium channel TRPV5 in mice was shown to result in severe hypercalciuria, compensatory intestinal hyperabsorption of calcium, and reduced bone thickness [30]. Later, a TRPV5 missense mutation was identified in a mouse model with dominant hypercalciuria [31]. In contrast, homozygous knock-out of basolateral NCX1 (SLC8A1) and PMCA1b (ATP2B1) in mice was shown to be embryonically lethal [32, 33].

Hypocalcemia

The etiology of calcium deficiency and hypocalcemia can most easily be divided into different entities according to the serum level of PTH [34]. Low levels of PTH indicate a primary dysfunction of the parathyroid gland with impaired or absent PTH production or release. Hereditary disorders involving an abnormal parathyroid gland function include primary hypoparathyroidism due to mutations in the *PTH* gene (isolated familial hypoparathyroidism 1, OMIM #146200), due to DiGeorge syndrome, caused by microdeletions on chromosome 22q11 (OMIM #188400), or due to

HDR syndrome (hypoparathyroidism, sensorineural deafness, renal dysplasia, OMIM #146255) with underlying mutations in the transcription factor GATA3.

However, inappropriately low or normal levels of PTH may also point to an activating mutation in the *CASR* gene encoding the Ca^{2+} sensing-receptor (CaSR) or in the *GNA11* gene encoding the accessory G-protein G-alpha-11 causing autosomal-dominant hypocalcemia type 1 and 2, respectively (ADH1, OMIM #601198; ADH2, OMIM #615361). These entities will be discussed in more detail below. ADH1 might be differentiated from the abovementioned disorders by determination of urinary calcium excretion: In contrast to low urinary calcium excretions found in primary forms of parathyroid function, urinary calcium excretions are inappropriately high in face of hypocalcemia in patients with ADH1.

Elevated levels of PTH in the presence of a normal renal function are also found in acquired calcium- and vitamin D-deficient rickets. Whereas hypocalcemia might also be an associated finding in renal Fanconi syndrome, it is rather uncommon in other disorders of the proximal tubule such as hypophosphatemic rickets, Dent's disease, or Lowe syndrome.

A heterogeneous group of rare hereditary disorders leading to the common feature of PTH end-organ resistance and hypocalcemia despite elevated PTH serum levels is pseudohypoparathyroidism (PHP1A OMIM #103580; PHP1B, OMIM #612462; PHP1C, OMIM #203330). Different genetic defects have been discovered as the underlying cause including loss of function mutations in the *GNAS* gene encoding the Gs-alpha isoform or methylation defects of the *GNAS* gene locus [35].

The extracellular calcium-sensing receptor (CaSR) plays an essential role in calcium and magnesium homeostasis by influencing not only PTH secretion but also by directly regulating the rate of calcium and magnesium reabsorption in the kidney. It was first cloned by Brown and colleagues in 1993 [36]. Along the distal nephron, the CaSR is expressed basolaterally in TAL and DCT as well as at both the apical and basolateral membrane of the collecting duct [37]. CaSR activation leads to coordinate changes in renal calcium and magnesium excretion and in water diuresis [38]. Dilution of the urine by decreasing aquaporin expression in the collecting duct is thought to minimize the risk of stone formation in the face of an increase in calcium and magnesium excretion.

The CaSR is a dimeric cell-surface protein belonging to the diverse group of G-protein coupled receptors. It has a large extracellular domain that was crystallized and shown to adapt a venus flytrap (VFT) conformation binding extracellular calcium at multiple sites [39]. Interestingly, recent data indicate additional anion binding sites through which phosphate is able to inhibit the CaSR in a noncompetitive antagonistic fashion and thereby induce PTH secretion from the parathyroid gland [40].

Via interaction with its transmembrane and intracellular domains, the CaSR acts through an intracellular signaling primarily mediated by the G proteins G_q and G_{11} [19, 41]. These activate phospholipase C resulting in the production of inositol 1,4,5 triphosphate and diacylglycerol (DAG). Downstream intracellular events finally result in a decrease in PTH release from the parathyroid gland and in an inhibition of renal tubular calcium absorption.

Calcium sensing is also influenced by the level of CaSR surface expression. The CaSR is internalized from the plasma membrane by clathrin-mediated endocytosis. A central component of these clathrin-coated vesicles (CCVs) is the adaptor protein 2 (AP2) that forms a heterotetrameric complexes of α, β, μ, and σ (AP2S1) subunits [42]. Several diseases associated with both activating and inactivating mutations in the *CASR* gene, *GNA11*, and *AP2S1* have been described.

Autosomal Dominant Hypocalcemia

Autosomal dominant hypocalcemia 1 (ADH1, OMIM #601198) is caused by activating mutations in the *CASR* gene. Affected patients typically manifest during childhood with seizures or carpopedal spasms. Laboratory evaluation reveals the typical combination of hypocalcemia and low PTH levels. Serum calcium levels are typically in a range of 6 to 7 mg/dL. In addition, many patients also exhibit moderate hypomagnesemia [43, 44]. Patients are often given the incorrect diagnosis of primary hypoparathyroidism on the basis of inappropriately low PTH levels. As indicated above, the differential diagnosis can be established by determination of urinary calcium excretions which are low in primary hypoparathyroidism, whereas ADH1 patients are thought to exhibit increased renal calcium excretions. The differentiation of ADH from primary hypoparathyroidism is of particular importance because treatment with active vitamin D in ADH may result in a dramatic increase in hypercalciuria and the occurrence of nephrocalcinosis and impairment of renal function. Therefore, therapy with active vitamin D or calcium supplementation should be reserved for symptomatic patients with the aim to maintain serum calcium levels just sufficient for the relief of symptoms [44].

Activating *CASR* mutations lead to a lower setpoint of the receptor or an increased affinity for extracellular calcium and magnesium. This inadequate activation by physiological extracellular calcium and magnesium levels results in diminished PTH secretion in the parathyroid gland as well as a decreased reabsorption of both divalent cations mainly in the cTAL of the kidney tubule. A severe degree of hypocalcemia and hypomagnesemia is observed in patients with complete activation of the CaSR at physiologic serum calcium and magnesium concentrations who may also exhibit a Bartter-like phenotype [45]. In these patients, CaSR activation inhibits TAL-mediated salt and divalent cation reabsorption to an extent that cannot be compensated in later nephron segments [45].

Genetic heterogeneity in autosomal dominant hypocalcemia (ADH2, OMIM #615361) was demonstrated in 2013 by discovery of heterozygous missense mutations in *GNA11* encoding the accessory G-protein $G_{\alpha 11}$ of the CaSR [46, 47]. The identified variants were shown to increase CaSR signaling and inositol 1,4,5-triphosphate synthesis resulting in a leftward-shift of the concentration-response curve with significantly lower EC_{50} values for extracellular Ca^{2+} [46].

Hypercalcemia

In contrast to hypocalcemia, hypercalcemia represents a rather uncommon finding in infancy and childhood but requires prompt diagnostic workup and targeted therapy [48, 49]. Hypercalcemia is defined as ionized Ca^{2+} levels above 1.35 mmol/L, usually with a concomitant elevation of total serum calcium levels above 2.7 mmol/L. While most children with a mild degree of hypercalcemia remain asymptomatic, more severe hypercalcemia can lead to a serious clinical disease pattern that may even be life-threatening. Symptoms of hypercalcemia include failure to thrive, weight loss, dehydration, fever, muscular hypotonia, constipation, irritability, lethargy, and disturbed consciousness. Cardiovascular findings may comprise bradycardia, shortened QT interval, and arterial hypertension (Table 2).

An impairment of renal function by volume contraction can further limit renal calcium elimination and therefore aggravate the excess in serum calcium levels. On the other hand, the increase of renal calcium excretion in hypercalcemic conditions is a risk factor for the development of nephrocalcinosis and stone formation.

The assessment of the patient`s past medical history should comprise medications including over-the-counter vitamin preparations and family history with a focus on disturbances in calcium metabolism, renal disease, and urolithiasis.

The etiology of hypercalcemia in children and especially infants significantly differs from that in adulthood where primary hyperparathyroidism and malignancy represent the most common underlying causes [50]. In early life, the time at which symptoms occur may yield an important information on the underlying etiology. Especially in infants, rare hereditary disorders should be considered in the differential diagnosis [48].

Table 2 Symptoms of acute hypercalcemia

	Arterial hypertension

The diagnostic work-up, next to a thorough medical history, requires comprehensive laboratory testing including molecular genetics. Next to the parallel measurement of serum and urine electrolytes, the determination of PTH and vitamin D metabolites represents the most important element. Potential diagnostic parameters are summarized in Table 3.

Inappropriately normal or elevated levels of PTH point to a primary defect in the parathyroid gland. Next to primary hyperparathyroidism which is extremely rare in infancy and childhood, hypercalcemia caused by elevated PTH might be caused by hereditary disorders of the CaSR or associated proteins. In contrast to dominant activating CaSR mutations as present in ADH1 (see above), inactivating CaSR mutations may be present in either heterozygous or homozygous/compound-heterozygous state leading to Familial Hypocalciuric Hypercalcemia 1 (FHH1) and Neonatal Severe Hyperparathyroidism (NSHPT),

respectively (see below). Genetic heterogeneity in FHH was demonstrated in 2013 by discovery of heterozygous mutations in *GNA11* (FHH2) and *AP2S1* (FHH3) [42, 46].

In face of an appropriate suppression of PTH, vitamin D metabolites should be evaluated. The determination of 25-OH-vitamin D_3 primarily helps to exclude overt vitamin D intoxication. While cut-off values vary in the literature, usually levels above 200 ng/mL are regarded as toxic [51]. Besides, serum levels of active 1,25-$(OH)_2$-vitamin D_3 are of critical importance for further diagnostic considerations. Elevated levels are not only observed in vitamin D poisoning, but also in disorders with extra-renal expression of 1-α-hydroxylase including granulomatous disease or subcutaneous fat necrosis. In these disorders, 1α-hydroxylase (CYP27B1) is expressed by monocytes and is not regulated by serum calcium, phosphate, PTH, and 1,25-$(OH)_2$-vitamin D_3, as in the kidney.

Acute therapeutic measures in hypercalcemic patients primarily aim at the lowering of serum calcium levels into the reference range resulting in a rapid relief of clinical symptoms. For this purpose, different pharmacologic approaches have been considered (Table 4).

Table 4 Therapy of hypercalcemia in children

General measures
Stop of vitamin D supplements
Calcium restriction in enteral and parenteral nutrition
Specific measures
Promotion of renal calcium excretion Furosemide 0.5–1 mg per kg body weight q6h
Inhibition of enteral calcium absorption/inhibition of vitamin D-conversion Glucocorticoids, that is, methylprednisolone ~1 mg per kg body weight q6h Sodium cellulose phosphate
Inhibition of calcium release from bone Bisphosphonates, that is, pamidronate 0.5–1 mg per kg body weight over 4–6h Calcitonin 4–8 IU/kg body weight
Inhibition of vitamin D-activation by 1α-hydroxylase Imidazole derivates, that is, ketoconazole 3–9 mg per kg body weight per day
Hemodialysis/hemofiltration

Before clarification of the underlying etiology, vitamin D supplements need to be stopped and, if adequate, a low-calcium diet should be implemented. A central component of every therapeutic strategy is a vigorous rehydration, usually performed via the intravenous route. Fluid amounts up to twice the daily requirements have been proposed. The pharmacologic treatment includes therapeutic measures to decrease calcium absorption from the intestine, to promote renal calcium excretion, as well as to inhibit calcium release from bone (Table 4). To increase renal calcium elimination, loop diuretics such as furosemide are widely used. Furosemide inhibits passive paracellular calcium reabsorption in the thick ascending limb by blocking active transcellular salt reabsorption. A fast and effective approach to inhibit enteral calcium absorption is the administration of glucocorticoids, that is, prednisolone. Next to this intestinal effect, glucocorticoids also inhibit the conversion of 25-OH-vitamin D_3 into active 1,25-$(OH)_2$-vitamin D_3, an effect that is of special importance in vitamin D-mediated hypercalcemia. Sodium cellulose phosphate (SCP) is a nonabsorbable cation exchange resin used for the removal of excess calcium from the body [52]. It was initially used in patients with so-called absorptive hypercalciuria in order to decrease renal calcium excretions and prevent stone formation [53]. In the acute phase of hypercalcemia, calcitonin may be used because of its prompt and pronounced effect on serum calcium levels; however, its therapeutic usefulness is limited by its short duration of action due to the development of end organ resistance. In the presence of intermediate to severe symptomatic hypercalcemia, bisphosphonates such as pamidronate are used [54]. If bisphosphonate therapy is considered, it is important to have the diagnostic work-up completed in advance to avoid misinterpretation of diagnostic tests for PTH and vitamin D metabolites. A class of drugs that are specifically used in vitamin D-mediated hypercalcemia are imidazole derivates such as ketoconazole [55]. Next to their antifungal effect, they also inhibit mammalian cytochrome P450 enzymes. Via inhibition of 1α-hydroxylase

(CYP27B1), they are able to effectively lower serum levels of active 1,25-$(OH)_2$-vitamin D_3 and consecutively normalize serum calcium levels. In single patients with extremely high serum calcium levels, hemofiltration and hemodialysis have been performed with success [56].

Hypercalcemia with Inappropriately High PTH

Familial hypocalciuric hypercalcemia (FHH; OMIM #145980, #145981, #600740)/Neonatal severe hyperparathyroidism (OMIM #239200)

Familial hypocalciuric hypercalcemia 1 (FHH1) as well as neonatal severe hyperparathyroidism (NSHPT) results from inactivating mutations of the CaSR present in either mono-allelic or bi-allelic state, respectively [57]. Genetic heterogeneity has been described in FHH with heterozygous variants in *GNA11* (FHH2) encoding accessory G-protein $G_{\alpha 11}$ of the CaSR and in *AP2S1* (FHH3) encoding adaptor protein $\sigma 1$ involved in CaSR recycling from the plasma membrane [42, 46]. Therefore, all three subtypes of FHH share the pathophysiology of a decreased CaSR-mediated calcium sensing. FHH patients normally present with mild to moderate hypercalcemia, accompanied by few if any symptoms and often do not require treatment. However, the occurrence of pancreatitis and chondrocalcinosis has been described in FHH patients [58]. Urinary excretion rates for calcium and magnesium are markedly reduced and serum PTH levels are inappropriately high. In addition, affected individuals also show mild hypermagnesemia [59].

In contrast to FHH, patients with NSHPT with two mutant *CASR* alleles usually present in early infancy with polyuria and dehydration due to severe symptomatic hypercalcemia. If unrecognized and not treated, hyperparathyroidism and hypercalcemia result in skeletal deformities, extraosseous calcifications, and severe neurodevelopmental deficit. Early treatment with partial-to-total parathyroidectomy therefore seems to be essential to prevent a negative outcome [60]. Serum phosphate levels are typically low due to increased PTH levels [61].

Hypercalcemia with Suppressed PTH and Inappropriately High 1,25-$(OH)_2$-Vitamin D_3

Idiopathic infantile hypercalcemia (OMIM #143880, #616963)

Idiopathic Infantile hypercalcemia (IIH) was first described in the 1950s after an epidemic occurrence in the United Kingdom (UK) [62, 63]. Affected infants clinically present with typical symptoms of severe hypercalcemia. Concomitant hypercalciuria typically leads to the development of early nephrocalcinosis. The laboratory analysis reveals serum calcium levels up to 5 mmol/L. Intact PTH is suppressed while levels of active 1,25-$(OH)_2$-vitamin D_3 are usually elevated or in the upper normal range. Early, a connection to exogenous vitamin D was suspected [64–66]. Some children exhibited a complex phenotype that became later known as the Williams Beuren syndrome [67, 68]. However, most hypercalcemic infants did not have syndromic features and were considered to be affected by a milder variant of the syndrome that was termed idiopathic infantile hypercalcemia (IIH) [62, 63].

The pathophysiology of IIH remained unknown until the discovery of loss-of-function mutations in the vitamin D catabolizing enzyme 25-OH-vitamin D_3-24-hydroxylase (CYP24A1) [69]. CYP24A1 is responsible for several sequential degradation steps that convert active 1,25-$(OH)_2$-vitamin D_3 into water soluble calcitroic acid [70, 71]. Loss-of-function mutations in the *CYP24A1* gene lead to an accumulation and increased action of active 1,25-$(OH)_2$-vitamin D_3. Functional studies *in vitro* demonstrated a complete loss of 24-hydroxylase enzyme function for most of the identified *CYP24A1* mutations [69]. In addition to the genetic analysis of the *CYP24A1* gene, the determination of 24-hydroxylated vitamin D metabolites by liquid chromatography/mass spectrometry (LC/MS) represents a quick and reliable test in the diagnosis of the carriers of two mutant *CYP24A1* alleles [72].

The critical role of a cumulative dose of exogenous vitamin D is underscored by the following observations. Under the most commonly used dose of 500 IU vitamin D_3 per day, symptoms usually develop after several months, most likely with an incomplete penetrance of the genetic trait. Higher doses of supplemental vitamin D most likely lead to an increased incidence of the disease in infancy and an earlier manifestation. Regimens using oral bolus doses of up to 600.000 IU cause symptoms of acute vitamin D toxicity in infants with CYP24A1 deficiency, while they are tolerated well by healthy individuals [73]. Finally, omitting vitamin D supplementation in a genetically affected infant due to symptomatic disease in the older sibling can prevent hypercalcemic episodes and the development of nephrocalcinosis [69].

After diagnosis of symptomatic hypercalcemia with inappropriately high levels of 1,25-$(OH)_2$-vitamin D_3, vitamin D prophylaxis is usually stopped and a low-calcium diet might be implemented. The restriction of dietary calcium has to be carefully monitored as it might lead to a defective mineralization of bones and may increase intestinal absorption of oxalates with a subsequent risk of stone formation. Next to these therapeutic measures, vigorous intravenous rehydration and strategies to reduce serum calcium levels as described above are used in symptomatic patients (Table 4).

Currently, it remains unclear why many affected individuals requiring acute treatment during infancy do not show recurrency of symptomatic hypercalcemia later in life. Potentially, compensatory mechanisms, that is, a down-regulation of 1α-hydroxylase (CYP27B1), are able to prevent excessive activation of vitamin D. Laboratory parameters reflecting disease activity, that is, a suppressed PTH and inappropriately high levels of 1,25-$(OH)_2$-vitamin D_3, are detectable for a long time during follow-up. Nephrocalcinosis persists; however, the impact on renal function deterioration is unclear. Interestingly, since the initial description of C*YP24A1* mutations, several groups were able to identify *CYP24A1* mutations also in adult patients with mild hypercalcemia, nephrocalcinosis, and recurrent kidney stone disease [74–76]. Therefore, compound-heterozygous/homozygous or only heterozygous mutations in the *CYP24A1* gene may represent a risk factor for the development of wider spectrum of diseases associated with an increased action of vitamin D.

Genetic heterogeneity in IIH was demonstrated by discovery of recessive mutations in *SLC34A1* encoding proximal-tubular sodium-phosphate co-transporter NaPi-IIa [77]. Patients with NaPi-IIa defects share phenotypic and biochemical features of patients with *CYP24A1* mutations though hypercalcemia is usually milder. In addition, they exhibit phosphate depletion and hypophosphatemia. The pathophysiology involves primary renal phosphate wasting, phosphate depletion, and suppression of the phosphaturic hormone FGF-23. FGF-23, next to its role in proximal-tubular phosphate reabsorption, negatively regulates vitamin D metabolism by inhibiting 1α-hydroxylase (CYP27B1) and promoting the degradation of active 1,25-$(OH)_2$-vitamin D_3 by 24-hydroxylase (CYP24A1) [77].

In addition to acute therapeutic measures also applied in patients with CYP24A1 defects, hypercalcemic patients with NaPi-IIa defects require phosphate supplementation in order to control calcium metabolism.

A significant subset of patients with NaPi-IIa mutations may also be diagnosed with isolated early nephrocalcinosis or present later in childhood or adolescence with nephrolithiasis [78]. Of note, prenatal renal calcifications secondary to *SLC34A1* mutations have been described and should be included in the differential diagnosis of fetal hyperechogenic kidneys [79].

Very similar biochemical changes as in NaPi-IIa deficiency have also been reported in patients with *SLC34A3* defects encoding the closely related proximal-tubular sodium-phosphate co-transporter NaPi-IIc [80]. Mutations in NaPi-IIc had initially been described in patients with hypophosphatemic rickets with hypercalciuria (HHRH) [81, 82]. Clinical manifestations related to hypercalcemia in infancy have not been reported yet in patients with *SLC34A3* defects. Patients with bi-allelic, but also mono-allelic *SLC34A3* mutations commonly present with nephrocalcinosis and/or kidney stones later in life [80].

Abstract

Under normal circumstances, about 90% of the 180 L/day glomerular filtrate is constitutively reabsorbed in the proximal tubule and descending limb of Henle's loop. According to the needs, the remaining 10% of the fluid is reabsorbed in the collecting duct by a tightly regulated process under control of arginine vasopressin (AVP). After binding of AVP to arginine vasopressin type 2 receptors (AVPR2) in the basolateral membrane of collecting duct cells, aquaporin-2 (AQP2) water channels are inserted into the luminal membrane of these cells, allowing water reabsorption and urine concentration. Disorders of water handling are characterized by disturbances of this AVP-regulated system. In congenital nephrogenic diabetes insipidus (NDI), the kidney cannot concentrate urine in response to AVP, as a result of loss-of-function mutations in genes encoding AVPR2 and AQP2, resulting in polyuria and polydipsia. In recent years, extensive research has led to increased understanding of the cellular defects in NDI, with important implications for future development of targeted treatment of the disorder, with hope for better outcomes in comparison to the conventional symptomatic therapy. The very rare nephrogenic syndrome of inappropriate antidiuresis (NSIAD), caused by gain-of-function mutations in the gene encoding AVPR2, is the mirror image of NDI. In this disorder, urinary dilution is impaired, independent of the presence or absence of AVP. In this chapter, the focus will be on the physiology of water handling in the collecting duct and on its disturbances in congenital NDI. The clinical details, differential diagnosis, genetics, and conventional and possible future therapies of NDI will be discussed in detail.

Introduction

Disorders of water handling in the kidney lead either to dehydration or to overhydration. The vast majority of these disorders are acquired. The inherited disorders of water handling comprise congenital nephrogenic diabetes insipidus, which is associated with dehydration, and its mirror image, the nephrogenic syndrome of inappropriate antidiuresis, associated with overhydration and the risk of hyponatremia. In this chapter, after a detailed discussion on the physiology of urine concentration, we will mainly focus on the clinical details, diagnostics, differential diagnosis, genetics, and treatment of congenital nephrogenic diabetes insipidus.

Physiology of Urine Concentration, Including Vasopressin-Regulated Water Permeability

The physiologic action of vasopressin on the renal collecting duct is one of the most intensively studied processes in the kidney. Arginine vasopressin (AVP, or antidiuretic hormone (ADH)) is synthesized on the ribosomes of the magnocellular neurons of the supraoptic and paraventricular nuclei of the hypothalamus as a large biologically inactive bound form. Within storage granules, the hormone is cleaved into the biologically active form and transported down the neuronal axons to the posterior pituitary and stored there. Following appropriate stimuli, AVP is secreted from the posterior pituitary to the circulation as biologically active hormone. AVP release is regulated by changes in plasma osmolality (by >2%) but can also occur in response to non-osmotic stimuli. These non-osmotic stimuli are generally related to changes in either total blood volume or the distribution of extracellular fluid. Patients with depleted effective circulating volume may secrete AVP even in the presence of low plasma osmolality. In addition, hypoxia, physical pain, emotional stress, and certain drugs (e.g., nicotine) influence the release of AVP.

There are also vasopressin-expressing neurons in the suprachiasmatic nucleus (SCN), and the circadian regulation of thirst and arginine vasopressin secretion protects against overnight dehydration. This is called anticipatory thirst. SCN vasopressin neurons project to thirst neurons in the organum vasculosum of the lamina terminalis (OVLT), where vasopressin is released as a neurotransmitter [36]. For example, the SCN opposes overnight adipsia by driving water intake before sleep and by driving the secretion of AVP and lowering body temperature to reduce water loss during sleep [37]. The anticipatory signals regulating thirst, sodium appetite, and hunger have now been described in experimental animals with optogenetic tools [4]. Thirst and AVP release are regulated by the classical homeostatic, interosensory plasma osmolality negative feedback as well as by novel, exterosensory, anticipatory signals. Decreases in blood vasopressin levels and thirst have been observed within minutes following water consumption, preceding and hence “anticipating” changes in plasma osmolality. These anticipatory signals for thirst and vasopressin release concentrate on the same homeostatic neurons and circumventricular organs monitoring the composition of blood. The lamina terminalis which is the median portion of the rostral wall of the third ventricle of the cerebrum is composed of three structures: the subfornical organ (SFO), the organum vasculosum of the lamina terminalis (OVLT), and the median preoptic nucleus (MnPO) (Fig. 1). Of these, SFO and OVLT lack the normal blood-brain barrier and, therefore, have direct access to circulating components including angiotensin II. The anticipatory signals from the oropharynx and gut are now well described: MnPO inhibitory neurons that coexpress glucagon-like peptide 1 receptor ($\mathrm{MnPO}^{\mathrm{GLP1r}}$) transmit oropharyngeal-induced satiation and send monosynaptic inhibition to $\mathrm{SFO}^{\mathrm{nNOS}}$ neurons (Fig. 1) [3]. Sensory stimuli from the oropharyngeal area are generally transported through cranial nerves V, VII, IX, and X to the central pattern generator within the nucleus tractus solitarius (NTS), which elicits swallowing action.

In its effector organ, the kidney, AVP binds to arginine vasopressin type 2 receptors (AVPR2) on the basolateral membrane of the principal inner medullary collecting duct cells and of the arcade cells. The arcades are long, highly branched renal tubule segments that connect distal convoluted tubules of several deep and mid-cortical nephrons to the origin of cortical collecting ducts. Upon binding of AVP, AVPR2 is activated and then stimulates GTP loading of the small GTPase αG_S – subunit of its coupled trimeric G-protein, eventually leading to dissociation of the G-protein

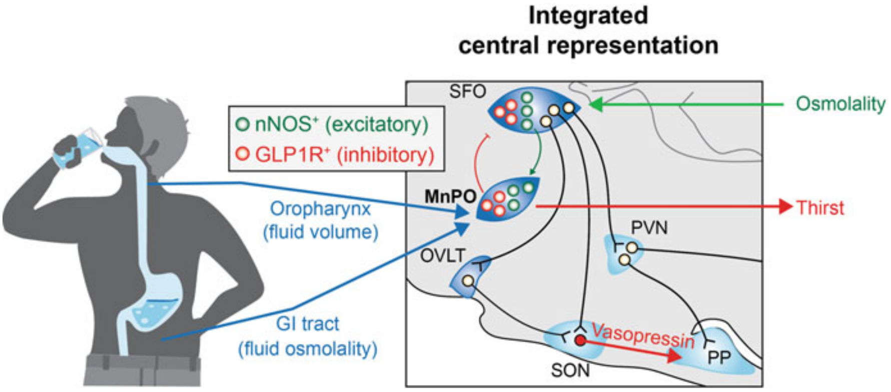

Fig. 1 **Anticipation for thirst and vasopressin regulation**. Following the detection of water in the mouth and its swallowing, there is a gut-to-brain signal: the osmolarity of the ingested fluid is perceived early in the digestive tract, probably in the small intestine or hepatic portal circulation, relayed by the vagus nerve and inhibits SFO^{Nos1} neurons well before any change in blood osmolality perceived by osmoreceptor cells. $MnPO^{GLP1R} \rightarrow SFO^{nNOS}$ forms an inhibitory circuit where $MnPO^{GLP1R}$ neurons are sensing volume in the oropharyngeal area and osmolarity in the gastrointestinal tract (represented schematically by blue arrows; modified from [126]). There is an integrated central representation of fluid balance at the level of individual MnPO neurons, which use this information to dynamically control drinking behavior and vasopressin secretion in real time

from the receptor (Fig. 2). GTP-αG_S can then bind to the membrane-associated adenylate cyclase 6 (AC6), activating it, primarily by stabilizing a catalytically competent form of the enzyme, which results in an increase in intracellular cyclic adenosine monophosphate (cAMP) from adenosine triphosphate (ATP) [118]. The elevated cAMP levels stimulate protein kinase A (PKA), leading to phosphorylation of AQP2 which in turn initiates a redistribution of aquaporin-2 (AQP2) water channels from intracellular vesicles to the apical plasma membrane, rendering this membrane water permeable. The increase in apical membrane permeability allows water to flow from the tubule lumen to the hypertonic medullary interstitium, via AQP2 in the apical membrane and via AQP3 and AQP4, constitutive water channels in the basolateral membrane. This then leads to the formation of concentrated urine. This process restores plasma osmolality and volume and is regulated by a negative feedback; upon restoration of the water balance, AVP release into the blood decreases; AQP2 is internalized, thus reducing water permeability of the collecting ducts and water reabsorption. AQP2 is retrieved to intracellular vesicles, resulting in either lysosomal degradation or intracellular storage and relocation to the plasma membrane upon restimulation with AVP. At the basolateral side of the collecting duct, AVP binding to AVPR2 can also stimulate mechanisms that lead to termination of signaling. Desensitization and internalization of AVPR2, regulated by β-arrestin, decrease the amount of receptors in the plasma membrane [87].

In recent years, our knowledge of the AQP2 dynamics in the cell has increased significantly. For further details, the reader is also referred to several excellent reviews on this subject (reviews in [11, 29, 47, 78, 80, 121]). AQP2 is one of the 13 members of the aquaporin family of water channels. After transcription, AQP2 is folded into its native monomeric conformation in the endoplasmic reticulum, and homotetramerization takes place [38]. The tetramers are forwarded to the Golgi apparatus, where two out of four monomers are complex N-glycosylated. These functional water channels are then stored in intracellular vesicles to be transported to the apical membrane [84].

AQP2 plays a key role in short-term regulation and long term-adaptation of collecting duct water permeability. Short-term regulation (within minutes) is mediated by PKA-dependent phosphorylation and intracellular translocation of AQP2 from intracellular vesicles to the apical

Fig. 2 **Intracellular signal transduction pathway initiated by AVP binding to AVPR2**. Upon binding of AVP, AVPR2 is activated and then stimulates GTP loading of the small GTPase αG_S – subunit of its coupled trimeric G-protein, eventually leading to dissociation of the G-protein from the receptor. Following the publication of Kobilka and colleagues [39], we have represented here the hallmark of the G-protein-coupled receptor (GPCR) activation as the outward movement of the cytoplasmic end of transmembrane domain 6 (TM6) that opens up a large intracellular cavity to accommodate the G-alpha 5 subunit from G_s, leading to nucleotide exchange and activation of the G-protein. GTP-αG_S can then bind to the membrane-associated adenylate cyclase 6 (AC6), activating it. The resulting cAMP-production stimulation activates PKA, which in turn phosphorylates its target proteins AQP2, Rho-GDI, and CREB1. The transcription factor CREB-1-p stimulates AQP2 transcription, Rho-GDI-p initiates actin reorganization required for AQP2 transport, and AQP2-p homotetramers are transported to the apical membrane. Syn-4 and VAMP2 are involved in the insertion of AQP2 tetramers in the apical membrane. There, they render the membrane permeable for water, which is reabsorbed from the passing pro-urine and transported back into the blood stream by AQP3 and AQP4. Rab5-mediated AQP2 endocytosis by clathrin-coated vesicles is triggered by short-chain ubiquitylation and leads to termination of the response. Internalized AQP2 vesicles are transported to early and late endosomes as well as multivesicular bodies (MVBs) for storage. From MVBs, they can then either be lysosomally degraded or recycled via the Rab-11-dependent slow recycling pathway. The cAMP pathway can also be stimulated independent of AVPR2 signaling, for instance, by activation of ß3 adrenergic receptors or PGE2,4 receptors

plasma membrane. Long-term adaptation is seen when circulating AVP levels are increased over a period of hours and involves a change in the total abundance of the AQP2 protein in collecting duct cells as a result of regulatory actions at the transcriptional or posttranscriptional level. Both short- and long-term modulations of AQP2 are extremely complex and still not fully understood processes.

Short-Term Regulation of Water Reabsorption in Collecting Duct

PKA-dependent phosphorylation at the cytoplasmic carboxy-terminal serine 256 residue (pS256-AQP2) is essential and sufficient to cause trafficking of AQP2 to the apical membrane [34]. Phosphorylation at other canonical phosphorylation sites in the carboxy-terminus of AQP2 (i.e., Ser264, Ser269, Ser261) is involved also but apparently less critical (review in [29]). Phosphorylation at Ser269 inhibits AQP2 endocytosis, resulting in increased retention of AQP2 at the apical plasma membrane. Phosphorylation at Ser261 plays an important role in sorting AQP2 to degradation pathways. Studies using oocytes as a model system indicated that for plasma membrane localization, three out of four monomers in an AQP2 tetramer need to be phosphorylated [50]. PKA is the main kinase for AQP2 phosphorylation, but other kinases may potentially participate in the regulation of AQP2 trafficking. Besides PKA sites, putative phosphorylation sites for Protein kinase G (PKG), Protein kinase C (PKC), and casein kinase II are also present in the AQP2 sequence. In addition, it has been shown that anchoring of PKA to PKA-anchoring proteins (AKAPs), which ensures targeting of PKA to AQP2-bearing vesicles, is another prerequisite for AVP-mediated AQP2 translocation [57].

Reorganization of the actin cytoskeleton is also required for AQP2 transport to and accumulation in the apical membrane. The actin cytoskeleton most likely provides a network that anchors the AQP2-bearing vesicles in the unstimulated cell. Vasopressin has been shown to depolymerize apical F-actin in rat inner medullary collecting duct, resulting in the fusion of AQP2-carrying vesicles with the apical membrane [111], indicating that reorganization of the apical actin network may be critical in promoting the trafficking of AQP2-bearing vesicles. Activation of small GTPase RhoA induces F-actin-containing stress fibers and tonically inhibits AQP2 trafficking. Rho inhibition through PKA-mediated phosphorylation of Rho-GDP dissociation inhibitor (Rho-GDI) is shown to be a key event for actin reorganization inducing AQP2 translocation [58].

The plasma membrane insertion of AQP2-containing vesicles in the apical membrane is similar to the process of synaptic vesicle fusion with the presynaptic membrane and involves vesicle (v) soluble NSF attachment protein receptors (SNAREs) and target membrane (t) SNAREs. The apical membrane-specific t-SNARE is syntaxin 4 (Syn-4), which interacts specifically with the v-SNARE protein VAMP2 located on the cytoplasmic side of AQP2-containing endosomal vesicles [66, 71, 85]. V- and t-SNARES are recycled by the AAA-type ATPase NSF.

AQP2 is internalized after removal of AVP stimulation when the water balance is restored. During this endocytotic process, AQP2 accumulates in clathrin-coated pits and is internalized via a clathrin-mediated process [114]. Endocytosis is regulated by short-chain ubiquitylation at lysine 270 (K270) in the AQP2 terminal tail [51]. The process of ubiquitylation of AQP2 involves several ubiquitin E3 ligases, including NEDD4, and the heat-shock protein 70 (Hsp70)-interacting protein CHIP [76, 119, 122]. Specificity of the endocytotic AQP2 internalization is mediated by Rab5 protein, an effector-binding factor involved in plasma membrane to early endosome transport [90]. To be available for recycling, AQP2-containing endosomes need to be redistributed to the perinuclear region. This process is mediated by dynein-dependent transport along microtubules [73]. From the endosomal system – early/late endosomes and/or multivesicular bodies (MVBs) – AQP2 is either recycled by the Rab11-dependent slow recycling pathway or marked for lysosomal degradation [113]. Prolonged K270 ubiquitylation induces MVB trafficking and localization to internal vesicles of MVBs followed by lysosomal degradation, while deubiquitylation increases localization to early endosomes and the limiting membrane of MVBs and enables AQP2 recycling [51, 102, 113].

Long-Term Regulation of Water Reabsorption in Collecting Duct

Long-term adaptation of collecting duct water permeability following AVP stimulation is mediated by changing the expression of AQP2 mRNA and protein (review in [48]). An increase in cAMP levels result in PKA-mediated phosphorylation and activation of a cAMP-responsive element-binding protein 1 (CREB-1), which increases AQP2 expression by enhancing its gene transcription. Evidence is accumulating that nuclear receptor transcription factors (i.e., PPARγ, FXR, GR, MR, LXRs) are also involved in the long-term regulation of water transport in renal collecting ducts by either up- or downregulating AQP2 gene transcription and expression (review in [29, 125]). In addition, micro-RNAs (i.e., miR-32 and miR-137) appear to be important posttranscriptional regulators of AQP2 protein abundance [53, 96].

Alternative Signaling Pathways

The AVP-dependent cAMP-PKA pathway is the canonical pathway to regulate AQP2 expression and trafficking. In recent years, it has been demonstrated that alternative pathways bypassing AVPR2 signaling may also influence AQP2 regulation and trafficking (reviews in [48, 78]). These alternative pathways are interesting since they may be targets for therapy of NDI. The cAMP pathway can be stimulated by the activation of other G-protein-coupled receptors (GPCRs), such as the prostaglandin receptors (EP2/EP4), the calcitonin receptor, the secretin receptor, and the β3-adrenergic receptor (reviews in [48, 78]). In addition, AQP2 trafficking and abundance are affected by the cAMP-exchange protein directly activated by cAMP (Epac) pathway. The latter pathway is suggested to be involved in the long-term regulation of AQP2, whereas the cAMP-PKA pathway has independent short-term effects. The AVPR2-elicited pathway can also be bypassed in a cAMP-independent way. For instance, activation the Cyclic guanosine monophosphate (cGMP) pathway by nitric oxide donors or atrial natriuretic peptide promotes AQP2 trafficking and membrane insertion, and activation of the Wnt5-frizzled receptor promotes AVP-independent AQP2 phosphorylation via intracellular calcium/calmodulin/calcineurin signaling [2].

Congenital Nephrogenic Diabetes Insipidus

Congenital nephrogenic diabetes insipidus (NDI) is a rare inherited disorder, characterized by insensitivity of the distal nephron to the antidiuretic effects of AVP. As a consequence, the kidney loses its ability to concentrate urine, which may lead to severe dehydration and electrolyte imbalance (hypernatremia and hyperchloremia).

Clinical Presentation

Patients with NDI have normal birth weight, and pregnancies are not complicated by polyhydramnios. The urine-concentrating defect in NDI is present from birth, and manifestations of the disorder generally emerge within the first weeks of life. With breast milk feedings, infants usually thrive and do not develop signs of dehydration. This is because human milk has a low salt and protein content and therefore a low renal osmole load. With cows' milk formula feedings, the osmole load to the kidney increases, resulting in an increased demand for free water. This is usually not provided by oral feeding, and therefore, hypernatremic dehydration appears. Polyuria and polydipsia, irritability, poor feeding, recurrent vomiting, and poor weight gain are usually the initial symptoms [21, 107]. Patients are eager to suck but may vomit during or shortly after the feeding. Dehydration is evidenced by dryness of the skin, loss of normal skin turgor, recessed eyeballs, increased periorbital folding, depression of the anterior fontanel, and a scaphoid abdomen. Intermittent high fever is a common complication of the dehydrated state, predominantly in very young children. Body temperature can be normalized by rehydration. Seizures can occur but are rare and most often seen during therapy, particularly if rehydration proceeds too rapidly. Constipation is a common symptom in children with NDI. Nocturia and nocturnal enuresis are common complaints later in childhood.

If untreated, most patients fail to grow normally. In a retrospective study of 30 male NDI patients, most children grew below the 50th percentile, most of them having standard deviation (SD) scores lower than −1 [68]. Some well-treated patients, however, may achieve normal adult height. Catch-up growth occurs at least in some patients after normalization of water and electrolyte balance, especially in those with adherence to treatment. Bone maturation is generally not delayed.

In a more recent European report on the long-term follow-up of patients with NDI, growth was improved compared with historic cohorts with median height SDS being −1.1 at presentation and − 0.9 SD at last follow-up and median weight SDS being −2.1 and 0.2, respectively [107]. Initial feeding problems and the ingestion of large amounts of low-calorie fluid resulting in a decreased appetite may play roles in failure to thrive seen in NDI. Furthermore, it is possible that repeated episodes of dehydration have some as yet undetermined negative effects on growth.

Intellectual disability has long been considered an important complication of untreated NDI and assumed to be a sequel of recurrent episodes of severe brain dehydration and cerebral edema caused by overzealous attempts at rehydration. Additional evidence underscoring the assumption that NDI has adverse effects on the cerebrum is provided by several reports describing intracranial calcifications in NDI patients [109]. Such lesions are generally considered to be the result of hemorrhage or necrosis. Most of the reported patients with cerebral calcifications were intellectually disabled. Nowadays, intellectual disability is rare due to earlier recognition and treatment of NDI. Exact estimates of the current frequency of intellectual disability under modern treatment are unknown. One psychometric study reported 2 of the 17 male NDI patients (aged 3–30 years) have a total intelligence quotient of more than 2 SD below the norm. Fourteen patients had an intelligence score within or above the normal range, and one patient had a general index score between −1 and − 2 SD [40].

The psychological development of NDI patients is influenced by a persistent desire for drinking and the need for frequent voiding, which compete with playing and learning. Therefore, many NDI patients are characterized by hyperactivity, distractibility, short attention span, and restlessness. In the psychometric study mentioned earlier, the criteria for attention deficit hyperactivity disorder were met in 8 of 17 tested NDI patients [40].

In a recent cohort of NDI patients, one of 36 patients had severe global developmental delay which was already noted at his presentation at 7 months, and 5 of 28 children in whom information on learning and behavior information was available had attention deficit hyperactivity disorder (ADHD) and/or learning difficulties and/or impaired concentration, pointing to overall improvement in mental and psychological development of individuals with NDI over the last decades [21, 107].

Urological complications are noted in 40%–50% NDI patients [20, 107]. Persistent polyuria can result in the development of megacystis, trabeculated bladder wall, hydroureter, and hydronephrosis [21, 68, 107]. Urinary tract distension may be seen on ultrasound examination even in infants and young children. Potential complications of urinary tract dilatation are rupture of the urinary tract, infection, intractable pain, improper bladder function, and/or kidney failure. These complications may occur as early as the second decade of life. Large-capacity hypotonic bladder dysfunction might require clean intermittent catheterization.

Patients should be trained to void regularly in order to assure that maximal urinary bladder capacity remains within normal range. Both patient groups with *AVPR2* and *AQP2* mutations can develop urinary tract dilatation and bladder dysfunction. Nocturnal enuresis usually persists longer than in healthy children due to pronounced polyuria. One study reported the median age at resolution being around 11 (range 5–16) years [107].

Chronic kidney disease stage 2 or higher is reported in about 20% of the patients; however, no case of end-stage kidney disease has been reported so far [21, 107].

Diagnostic Procedures

The observation of polyuria in a dehydrated infant, together with the finding of a high serum sodium concentration and inappropriately dilute urine (Uosm/Posm), provides presumptive evidence for a renal concentrating defect. To confirm the concentrating defect and to distinguish the renal form of diabetes insipidus from the central form, a vasopressin test is performed with 1-deamino-8-D-arginine vasopressin (DDAVP), a synthetic analogue of the natural arginine vasopressin that produces a high and prolonged antidiuretic effect. In the test, DDAVP (10 μg for infants <1 year old, 20 μg for children >1 year old) is administered intranasally. Urine is collected during the subsequent 5.5 hours. The first collected portion of the urine should be discarded. The maximal urine osmolality in any collected aliquot is chosen as a measure of the concentrating capacity. After DDAVP administration, NDI patients are unable to increase urinary osmolality, which remains below 200 mOsm/kg H_2O (normal values: <1 year old >600, between 1 and 2 years old between 600 and 800, >2 years old >800 mOsm/kg H_2O) and cannot reduce urine volume or free-water clearance.

Performing a water restriction test is not recommended for the diagnosis of NDI as it can lead to pronounced dehydration and unneeded suffering of the patients.

Plasma vasopressin levels are normal or only slightly increased in affected children. Other laboratory findings have been described, which mainly result from chronic dehydration. Serum sodium concentration is generally elevated and may be above 170 mmol/L. There is also an increase in serum chloride concentration and retention of urea and creatinine. All values normalize by adequate rehydration. In addition, reduced glomerular filtration rate (GFR) and renal blood flow can return to normal when a normal hydration state has been achieved.

The primary congenital form of NDI has to be differentiated from central diabetes insipidus (due to lack of AVP) and from the secondary or acquired forms, which are much more common. In our experience, the urinary osmolality obtained after DDAVP administration in secondary disorders is always higher than in NDI.

Secondary Nephrogenic Diabetes Insipidus

In addition to primary forms of congenital NDI, a few cases of secondary inherited NDI have been reported [11] (Table 1). These patients have Mendelian diseases that affect tubular function with NDI as a secondary complication. In some such patients, the NDI symptoms dominate the clinical picture, leading to an initial misdiagnosis, with the true underlying cause of disease subsequently identified. Most of the primary diseases associated with secondary NDI, such as Bartter syndrome and apparent mineralocorticoid excess, are associated with hypokalemia and hypercalciuria. Patients with polyhydramnios, hypercalciuria, and isosthenuria have been found to bear *KCNJ1* (ROMK), *SLC12A1* (NKCC2), and *MAGED2* mutations. Patients with polyhydramnios, profound polyuria, hyponatremia, hypochloremia, metabolic alkalosis, and sensorineural deafness were found to bear *BSND* (Barttin) mutations. These studies demonstrate the critical importance of the proteins ROMK, NKCC2, and barttin in transferring NaCl to the medullary interstitium and thereby generating, together with urea, a hypertonic milieu.

Acquired Nephrogenic Diabetes Insipidus

Although the hereditary forms of NDI are relatively rare, a wide range of pathologic conditions and drug treatments can lead to acquired NDI (Table 1). In our experience, the urine osmolality obtained after DDAVP administration in these acquired disorders is always higher than in congenital NDI. All these disorders have been shown to coincide with decreased expression of AQP2 or deregulated AQP2 trafficking to the apical membrane [32, 63, 72, 105]. For instance, prolonged

Table 1 Causes of secondary or acquired nephrogenic diabetes insipidus

Monogenetic diseases associated with secondary NDI

Hypokalemia

treatment with lithium, the drug of choice for treating bipolar disorders and prescribed to 1 in 1000 of the population, results in the development of NDI in at least 20% of treated individuals [120]. The development of lithium-NDI is believed to occur in two phases. In the first short-time phase, lithium causes a decrease in AQP2 expression (review in [55]). Lithium enters the cells via epithelial sodium channel (ENaC) and accumulates in principal cells. How lithium downregulates AQP2 is not clear but likely involves glycogen synthase kinase 3 (GSK3)-β, which is important in AVP-regulated antidiuresis and is inhibited by lithium. GSK3 inhibitors other than lithium also reduce AQP2 expression in collecting duct cell cultures, and ablation of GSK alpha or beta in mice causes an inability to concentrate urine by dehydration or DDAVP [19]. Lithium also influences AQP2-mediated water reabsorption by increased tubular release of prostaglandin E2. In the second phase, lithium reduces the percentage of principal cells in the collecting duct to the advantage of intercalated cells, involved in acid-base homeostasis [18]. The exact contribution of this collecting duct remodeling in the lithium-induced resistance to vasopressin remains to be elucidated. Autophagic degradation of aquaporin-2 has been implicated in hypokalemia and hypercalcemia-induced NDI [19].

Nephrogenic Diabetes Insipidus: Genetics

Three different inheritance patterns of congenital NDI have been recognized. In most cases (about 90%), NDI is transmitted as an X-linked recessive trait (MIM304800). In these families, female carriers who are usually unaffected, transmit the disease to their sons, who display the complete clinical picture. In 1992, mutations in *AVPR2* were shown to underlie X-linked NDI [89, 103]. In a minority of families (about 10%), the transmission and phenotypic characteristics of NDI are not compatible with an X-linked trait. In these families, females display the complete clinical picture of NDI and are clinically undistinguishable from affected male family members. Family pedigrees suggested the existence of both an autosomal recessive (MIM 222000) and an autosomal dominant form (MIM 125800) of NDI. It was subsequently demonstrated that both autosomal forms of NDI are caused by mutations in *AQP2* [22, 81]. The prevalence of NDI is not exactly known, but the disease is assumed to be rare. The estimate of the prevalence of NDI in Quebec, Canada, is 8.8:1,000,000 males. However, owing to chance population genetic events, such as a founder effect, the incidence of NDI is elevated in certain regions, for example, in Utah and Nova Scotia [11].

X-Linked Nephrogenic Diabetes Insipidus: Mutations in AVPR2

The X-linked form of NDI is caused by loss-of-function mutations in *AVPR2* (MIM 300538) (reviews in [8, 11, 46, 59, 80, 121]). *AVPR2* is a relatively small gene, consisting of three exons separated by two short intervening sequences (introns); two isoforms are known that are generated by alternative splicing [30]. *AVPR2* is localized on the X chromosome on locus Xq28. The cDNA encodes a receptor protein of 371 amino acids, has a predicted molecular mass of approximately 40 kDa, and shares the general structure of a G-protein-coupled receptor consisting of seven hydrophobic transmembrane helices, connected by extracellular and intracellular loops. The receptor contains one unique consensus sequence site for N-linked glycosylation in the extracellular amino-terminus [42] and phosphorylation sites for G-protein-coupled receptor kinases (GRK) represented by a serine cluster in the carboxy-terminus [43]. The amino-terminal part of the protein including the first transmembrane domain and the positively charged first intracellular loop are important for proper insertion and orientation in the membrane [110]. A conserved glutamate-dileucine motif in the intracellular carboxy-terminal part of the receptor is essential for receptor transport from the endoplasmic reticulum (ER) to the Golgi apparatus [61]. Two conserved adjacent cysteines in the C-terminus are palmitoylated, thereby anchoring the carboxy-tail to the plasma membrane and controlling the tertiary structure of this region of the receptor [110].

To date, there are more than 280 distinct disease-causing mutations in *AVPR2*, and the number is constantly increasing (reviews in [7, 59, 80, 121], and www.hgmd.org). The mutations are not clustered in one domain of the AVPR2 but are scattered throughout the protein, except for the part coding for the N- and C-terminal tails of the receptor. More than 50% of the mutations are missense mutations; nonsense mutations (8%), splice site mutations (1%), small deletions (18%), small insertions/duplications (7%), small indels (2%), large gene deletions (8%), large insertions/duplications (1%), and complex rearrangements (2%) account for the remainder of mutations (reviews in [7, 46, 59, 80, 121], and www.hgmd.org). Several mutations (p.Asp85-Asn, p.Val88Met, p.Arg113Trp, p.Tyr128Ser, p.Arg137His, p.Ser167Leu, p.Arg181Cys, p.Arg202Cys, p.Ala294Pro, and p.Ser315Arg) are recurrent as evidenced by the fact that these mutations were found on different haplotypes in ancestrally independent families. The most frequent of these recurrent mutations (p.Asp85Asn, p.Val88Met, p.Arg113Trp, p.Arg137His, p.Ser167-Leu, p.Arg181Cys, p.Arg202Cys) occur at potential mutational hotspots [8].

AVPR2 mutations seem to be present in all ethnical groups tested with no preference of one mutation for any ethnic group over others. However, two founder mutations, the p.Trp71* "Hopewell" mutation in Ulster Scott immigrants and the p.Leu312* in a large Utah pedigree, result in an increased prevalence of X-linked congenital NDI in their descendants in certain communities in Nova Scotia, Canada, and Utah [33].

The molecular mechanism underlying the renal insensitivity for AVP differs between mutants. As upcoming pharmacological treatments for NDI likely depend on the underlying mechanism, GPCR mutations in general and *AVPR2* mutations in particular have been divided in five different classes according to their cellular fate ([98], review in [78]).

Class I comprises all mutations that interfere with proper transcription, mRNA processing, and translation, resulting in truncated proteins that are often rapidly degraded, such as splice site, frameshift, and nonsense mutations [98]. Class II mutations are missense or insertions/deletions of one or more nucleotide triplets, resulting in fully translated proteins. Due to the mutation, however, mutant receptors are misfolded and retained in the endoplasmic reticulum (ER), as the ER is the organelle that has the cellular quality control over proper folding and maturation of synthesized proteins. Misfolded proteins are subsequently mostly targeted for proteasomal degradation [26]. Intracellular entrapment of missense AVPR2 mutants and their rapid degradation likely represent the most important cause of NDI, as more than 50% of the *AVPR2* mutations are missense mutations and cellular expression revealed that most of these result in ER-retained proteins. Class III mutations result in plasma membrane-expressed receptors with reduced affinity for the stimulatory G_s protein. Mutations in this group are missense mutations and in-frame deletions, mostly located in transmembrane and intracellular domains [99]. Class IV mutations have low affinity for

AVP [99]. Finally, class V mutations are missorted to incorrect cellular compartments, like arrestin-positive endocytotic vesicles [5]. Sometimes, mutants do not exert a full phenotype of a particular class and then often also show features of another class. For example, some AVPR2 missense mutants are partially ER-retained (class II) but are also partially expressed in the plasma membrane, where they might show a reduced G-protein coupling (class III) or AVP binding (class IV). As such, it provides an explanation for the observed small antidiuretic response to high doses of DDAVP in NDI patients harboring such mutations [92].

Nephrogenic Syndrome of Inappropriate Antidiuresis

NSAID, with four identified *AVPR2* gain of function mutations: R137C, R137L, F229V, and I130N, is the mirror image of NDI. [7]. In NDI, the kidneys cannot concentrate the urine, whereas in NSIAD, urinary dilution is impaired, independent of the presence or absence of vasopressin. Consequently, patients with NDI are at risk of hypernatremic dehydration, whereas hyponatremia is a typical manifestation of NSIAD, mimicking the syndrome of inappropriate antidiuresis (SIADH); unlike SIADH, AVP levels are usually low or undetectable in NSIAD [28]. The diagnostic pathways also mirror: in NDI, an agonist for the AVPR2, such as synthetic V_2-vasopressin analogue 1-deamino-8-D-arginine vasopressin (DDAVP), is given to assess the ability of the kidneys to concentrate urine. Conversely, administration of an AVPR2 antagonist, such as tolvaptan, provides an assessment of urinary dilution capacity in patients suspected of NSIAD.

Recently, it was shown that NSIAD can also be caused by mutations in Gsα-coding *GNAS* gene. Miyado et al. reported two families with a dominantly inherited form of NSIAD segregating with the GNAS variants p.F68_G70del and p.M255V [79]. The *GNAS* mutation p.F376V was reported in two unrelated patients with hyponatremia, and it was associated with additional clinical symptoms, suggesting gain of function not only of AVPR2 but also of other GPCR, including the lutropin (LHGR) and parathyroid hormone (PTH1R) receptors [10]. The severity of the phenotype in the patients with the dominantly inherited mutations was quite variable: some patients presented with seizures in early childhood associated with euvolemic hyponatremia, inappropriately elevated urine osmolality, and suppressed vasopressin levels. Other patients had no apparent symptoms and were normonatremic when investigated, but they had elevated urine osmolality despite suppressed vasopressin levels and a history of spontaneously low fluid intake. Symptomatic family members were treated with fluid restriction with normalization of hyponatremia.

Genotype-Phenotype Correlations in X-Linked NDI?

Almost all pathogenic variants in *AVPR2* result in a uniform clinical NDI phenotype with polyuric manifestations in the first weeks of life and poor growth. There are, however, a few exceptions to this rule. Several mutations appear to be associated with a milder form of NDI, characterized by a later manifestation, not at birth but later in childhood, and without growth retardation. At present, 18 *AVPR2* pathogenic variants resulting in partial NDI have been reported (Table 2; review in [59]).

Intrafamilial variability of the X-linked NDI phenotype has also been described. A nice example is the case described by Kalenga et al., who reported a Belgian family in which the p.Arg137His pathogenic variant was associated with severe NDI in the proband but with very mild NDI in his affected brother [49]. Genetic and/or environmental modifying factors are likely to account for this intrafamilial phenotype variability.

The Autosomal Recessive and Autosomal Dominant Forms of Nephrogenic Diabetes Insipidus: Mutations in the Aquaporin-2 Water Channel

Both the autosomal recessive and the autosomal dominant types of NDI are caused by mutations in the *AQP2* water channel gene (MIM 107777;

Table 2 *AVPR2* pathogenic variants resulting in partial NDI

Pathogenic *AVPR2* variants	Effect of the variant(s)	References
p.Asn317Lys p.Asn317Ser p.Asn321Tyr p.Met311Val	Reach the cell surface with impaired ligand capacity and partial AVP/DDAVP binding	[83]
p.Asp85Asn	Decreased ligand-binding affinity and decreased coupling to G_s	[104]

p.Ser334del p.Tyr128Ser p.Thr273Met p.Ser329Arg	Impaired intracellular trafficking	[27, 70, 116]
p.Arg104Cys	Decreased AVP binding most likely due to conformational changes	[27]
p.Leu161Pro c.276A > G (splice site)	Unknown	[123], [108]

GenBank accession number z29491). Human *AQP2* is a small gene consisting of four exons, comprising 5 kb genomic DNA. The 15 kb mRNA encodes a protein of 271 amino acids which has a predicted molecular weight of 29 kDa [35]. AQP2 belongs to a family of integral membrane proteins, aquaporins, which function as selective water transporters throughout the plant and animal kingdom. In mammals, 13 different aquaporins have been identified to date, eight of which (aquaporins 1–4, 6–8, and 11) are highly expressed in the kidney. In the plasma membrane, AQP2 exists as a homotetramer, with each monomer containing a water pore. Each AQP2 monomer has six membranes spanning α-helical domains and intracellular N- and C-termini. The six transmembrane helices are connected via three intracellular loops (A, C, and E) and two extracellular loops (B and D), the latter containing highly conserved Asn-Pro-Ala (NPA) sequence motifs. The six transmembrane helices surround a single, narrow water-conducting channel, while the two extracellular loops fold into the membrane from opposite sites with their NPA motifs forming a constriction in the middle of the permeation channel. Another conserved structural feature, the aromatic/arginine (ar/R) constriction site located at the extracellular side of the channel, acts as a selectivity filter, preventing permeation of all molecules bigger than water ([31], review in [29]). AQP2 is exclusively localized in the apical membrane and a subapical compartment of collecting duct cells. It is upregulated by dehydration or AVP, indicating that it is the AVP-regulated water channel.

To date, 52 putative disease-causing mutations in *AQP2* have been identified in families with autosomal recessive NDI (reviews in [8, 59, 78, 121]). These include 42 missense mutations, two nonsense mutations, two small deletions, and four splice site variants. Most mutations are found between the first and last transmembrane domain of AQP2. Expression studies in *Xenopus laevis* oocytes have revealed that most *AQP2* missense mutations that cause recessive NDI are class II mutations. Thus, these mutations lead to misfolding of the mutant protein, retention in the endoplasmic reticulum (ER), and rapid degradation of *AQP2* (review in [121]). When overexpressed in oocytes and Chinese hamster (CHO) cells, six of these AQP2 mutants (A147T, T126M, G64R, L22V, A47V, and T125M) confer water permeability [74, 117]. This indicates that at high expression levels, these AQP2 mutant proteins escape from the ER and are routed to the plasma membrane, where they are functional. In terms of possible treatment strategies, these results are of high importance, since they suggest that functional channels may be stimulated to reach the plasma membrane by restoring mutant trafficking.

One AQP2 missense mutant, P262L, located in the AQP2 C-terminal tail, a region until then believed to result in dominant NDI, surprisingly was found to be involved in recessive NDI [23]. In cell biological experiments, it was shown that the P262L mutant is a functional water channel that forms hetero-oligomers with wt-AQP2. These wt-AQP2/AQP2-P262L heterotetramers are located in the apical membrane, indicating that the apical sorting of wild-type AQP2 is dominant over the missorting signal of AQP2-P262L. This is different from dominant NDI, because in this form mutants retain wt-AQP2 in intracellular locations (see below). The recessive inheritance in the two patients encountered (patients were heterozygous for a R187C or A190T mutation on one allele, combined with a P262L mutation on the other allele) can be explained as follows: AQP2-R187C and AQP2-A190T are retained in the ER and do not interact with AQP2-P262L. AQP2-P262L folds properly and assembles in homotetramers but will be retained mainly in intracellular vesicles. The consequent lack of sufficient AQP2 proteins in the apical membrane of the patients' collecting duct cells explains their NDI phenotype. In the parents coding for wt-AQP2 and AQP2-R187C or AQP2-A190T, wt-AQP2 will not interact with either mutant but will form homotetrameric complexes, of which the insertion into the apical membrane will be regulated properly by vasopressin and will give a healthy phenotype. In the parents coding for wt-AQP2 and AQP2-P262L, both proteins likely assemble into heterotetramers. The dominancy of wt-AQP2 sorting on the localization of AQP2-P262L will result in proper AVP-regulated trafficking of the heterotetrameric complexes to the apical membrane and will also give a healthy phenotype [23].

More than ten families have been described with autosomal dominant NDI, initially uncovered due to father-to-son transmission of the disease. In these families, subsequent sequencing of *AQP2* revealed putative disease-causing mutations in one *AQP2* allele. At least 13 pathogenic variants that give rise to autosomal dominant NDI have been described. These are six missense variants, one 1-bp insertion, and six small deletions [59, 78, 121]. All mutations causing dominant NDI are located in coding region of the C-terminal tail of AQP2, which is not part of the pore-forming segment, but contains important sorting signals that govern intracellular transport of the protein [99]. Indeed, all functionally tested mutant AQP2 proteins found in dominant NDI appeared to be folded functional water channels that were sorted to other subcellular locations in the cell than wt-AQP2, e.g., late endosomes/lysosomes and the basolateral membrane. Because none of these mutants were misfolded, they were, in contrast to AQP2 mutants in recessive NDI, able to interact and form heterotetramers with wt-AQP2. Due to this wt-mutant interaction and the dominancy of the missorting signals in the mutant protein, the wt-mutant complexes are also missorted. Formation of heterotetramers with wt-AQP2 has been shown for most of the dominant AQP2 mutants. For instance, expression studies in polarized cell lines have revealed the dominant AQP2- E258K mutant is routed to the Golgi complex or late endosomes/lysosomes [81]. In co-expression studies with wild-type AQP2, a dominant-negative effect was observed, caused by impaired routing of wild-type AQP2 to the plasma membrane after hetero-oligomerization with the E258K mutant [52]. Mistargeting to the basolateral membrane has been reported for the AQP2-721delG, AQP2–763-772del, AQP2–812-818del, and AQP2–779-780insA mutants [62, 75]. TheAQP2-727delG mutant was shown to interfere with the routing of wild-type AQP2 to the apical membrane by its mistargeting to the basolateral membrane and late endosomes/lysosomes [75]. The loss of appropriate AQP2 heterotetramer trafficking in dominant NDI is caused by several mechanisms. The phosphorylation site at Ser256, serving as an introducible apical sorting signal, may be inactivated, overruled by basolateral sorting signals, or reprogrammed to induce basolateral sorting, all causing intracellular misrouting (review in [121]).

One-sixteenth of all tetramers formed are wt-AQP2-only tetramers explaining the relatively milder phenotype in autosomal dominant NDI compared to autosomal recessive NDI [24, 52, 75].

Recently, Calvanese et al. using an in silico automated method for modeling point mutations in protein structures, classified *AQP2* mutations into four main groups according to their molecular effect: mutations affecting (1) the pore, (2) tetramer assembly, (3) monomer folding, and (4) signal loss for protein phosphorylation [16]. The majority of the *AQP2* mutations they modelled are known to cause autosomal recessive NDI (12/14), while two mutations cause autosomal dominant NDI. Their findings were in line with the results of in vitro functional studies mentioned above. Remarkably, they also revealed a clear correlation between the type of mutation-induced structural defect and the experimentally observed phenotypes; mutations affecting the monomer folding cause the most severe phenotypes. These mutants are nonfunctional due to their misfolding and retention in the ER. The functionality of the mutants affecting the NPA motifs and the ar/R selectivity filter is also seriously impeded. However, mutations affecting other features of the pore, such as its dimension, or mutations affecting the tetramer assembly are associated with milder phenotypes, with resulting mutant AQP2 proteins partially retaining their water channel functionality.

Differential Diagnosis between the X-Linked and the Autosomal Forms of NDI

With a few exceptions, no differences in clinical symptoms between X-linked and autosomal recessive forms of NDI can be observed nor in the time of onset of the disease. Only in a minority of patients with the X-linked form of NDI, namely, those individuals carrying *AVPR2* mutations with partial insensitivity to AVP (Table 2), the disease onset is not directly after birth but later in childhood. In general, the initial symptoms in most autosomal dominant cases also appear later in childhood.

Male patients with X-linked NDI can be discriminated from patients with autosomal recessive NDI on the basis of their extrarenal reaction to the intravenous administration of the synthetic AVPR2-vasopressin analogue 1-deamino-8-D-arginine vasopressin (DDAVP). Patients with autosomal recessive NDI show a decrease in blood pressure, accelerated heart rate, and increases in von Willebrand factor, factor VIII, and tissue-type plasminogen activator levels, whereas in all studies of patients with X-linked NDI, these extrarenal responses are absent as a result of an extrarenal mutant AVPR2 [67]. In female patients, the interpretation of this intravenous DDAVP test is more complicated. Although absence of the extrarenal responses to intravenous administration of DDAVP in females clearly points to the presence of an AVPR2 defect, a normal response cannot be interpreted as indicative of a defect beyond AVPR2 and thus an AQP2 defect. The discrepancy between the renal and extrarenal response to DDAVP in these female *AVPR2* mutation carriers might be explained by variability in the pattern of X-inactivation between different tissues.

Nephrogenic Diabetes Insipidus in Females

Several families have been described in which females show classical clinical and laboratory features of NDI. After the identification of *AQP2* mutations as a cause for autosomal recessive NDI and in some cases for autosomal dominant NDI, a satisfying explanation for the complete manifestation of the disease in some females had been found. However, several families have been reported in which symptomatic females do not have an AQP2 defect but are heterozygous for an AVPR2 defect [27, 97]. In some of these women, maximal urinary osmolality after DDAVP administration does not exceed 200 mosmol/L. Of interest, in some of the reported families, asymptomatic female family members shared the same *AVPR2* mutation with the manifesting females. The most likely explanation for the existence of different phenotypes in carriers of an *AVPR2* mutation, varying from no symptoms to complete manifestation of the disorder, is skewed X-inactivation [77]. This hypothesis was underlined by studies investigating the X-inactivation patterns in peripheral blood leukocytes of female carriers via the detection of a methylated trinucleotide repeat in the human androgen receptor gene [106]. In asymptomatic females, random X-inactivation was found, while in most female carriers who showed clinical NDI symptoms, skewed X-inactivation patterns occurring preferentially to normal X alleles were recognized. In a few females with overt clinical NDI, however, random X-inactivation was identified [82].

In conclusion, clinical NDI phenotypes may correlate with the X-inactivation patterns in females with heterozygote *AVPR2* mutations. In some female carriers, however, the clinical phenotype cannot be predicted by evaluation of X-inactivation patterns in peripheral blood cells, probably due to the fact that X-inactivation ratios within an individual may vary between different tissues.

Nephrogenic Diabetes Insipidus: Treatment

Conventional Treatment

Symptomatic treatment of NDI is aimed to achieve normovolemia by replacing urinary water losses and reducing urinary volume. Adequate supply of fluid to prevent dehydration is the most important component of the therapy. For reducing urine output, a low-solute diet is applied to diminish the renal osmole load and decrease obligatory water excretion. Initially, a diet low in sodium (1 mmol/kg per day) as well as protein (2 g/kg per day) was recommended. However, severe limitations of dietary protein may introduce serious nutritional deficiencies. Therefore, it is preferable to prescribe dietary restriction of sodium only.

Diuretics such as hydrochlorothiazide (2–4 mg/kg per 24 hours) were the first class of drugs shown to be effective in lowering the urine volume in NDI. When combined with a reduction of salt intake, hydrochlorothiazide reduces urine volume by 20%–50% of baseline values. However, thiazide-induced hypokalemia may cause further impairment or urine concentrating ability in patients with NDI. Another possible risk associated with hypokalemia is cardiac arrhythmia. Simultaneous administration of potassium salt is therefore advised in patients with hypokalemia. Very low daily sodium intake in combination with thiazide diuretics should be avoided to prevent the development of hyponatremia.

There is ample evidence that the combined administration of hydrochlorothiazide with either a prostaglandin-synthesis inhibitor such as indomethacin (2 mg/kg per 24 hours) or the potassium-sparing diuretic amiloride is much more effective in reducing urine volume than the thiazide diuretics alone [44, 60]. Prolonged use of prostaglandin-synthesis inhibitors, however, might be complicated by gastrointestinal and hematopoietic side effects. Gastrointestinal complaints and complications include anorexia, nausea, vomiting, abdominal pain, ulceration, perforation, and hemorrhage. Hematopoietic reactions include neutropenia, thrombocytopenia, and, rarely, aplastic anemia. In addition, renal dysfunction has been described during indomethacin therapy, most often consisting of a slight reduction in GFR.

In patients who are not tolerating indomethacin, selective inhibitors of cyclooxygenase-2 (COX-2) might be helpful [91]. Caution in using indomethacin and selective COX-2 inhibitors in NDI is warranted as their administration can potentially lead to the acute deterioration of renal function in dehydrated patients.

Amiloride counterbalances the potassium loss from prolonged use of thiazides and thus prevents hypokalemia. Since amiloride appears to have only minor long-term side effects, the combination of hydrochlorothiazide (2–4 mg/kg/24 hours) with amiloride (0.3 mg/kg/24 hours) is the first choice of treatment. Our personal experience of more than 20 years with the amiloride-hydrochlorothiazide combination, however, indicates that amiloride is less well tolerated in young children below the age of 4–6 years because of persistent nausea. Therefore, we advise the temporary use of the combination of indomethacin-hydrochlorothiazide in these young children.

For a long time, the following mechanism for the antidiuretic effect of thiazides in NDI has been proposed: thiazides reduce sodium reabsorption in the distal tubule by inhibition of the NaCl cotransporter (NCC). This subsequently results in increased sodium excretion, extracellular volume contraction, decreased glomerular filtration rate, and increased proximal sodium and water reabsorption. Consequently, less water and sodium reach the collecting tubules, and less water is excreted. This long-standing hypothesis has been challenged by Magaldi, who reported new insights into the possible mechanism of action, based on microperfusion studies in rat inner medullary collecting duct (IMCD) [69]. In these studies, it was shown that in the absence of vasopressin, hydrochlorothiazide, when added to the luminal side, increased osmotic and diffusional water permeabilities, thus decreasing water excretion. When prostaglandins were added, the effect of thiazides decreased. This finding may offer one explanation why indomethacin potentiates the effect of thiazides in NDI [69]. Antidiuretic effect of thiazides is associated with an increase in AQP2 expression in collecting duct cells [54]. Long-term side effects of chronic thiazide administration such as hyperuricemia, alterations in serum lipid spectrum, and glucose intolerance should be monitored.

Although the drugs mentioned above reduce urine excretion, they are unable to achieve urine volumes produced in healthy individuals. Therefore, many young patients with NDI require nasogastric tube or gastrostomy to provide adequate nutrition and fluid supply [20]. Consequently, current research focuses on methods to treat NDI on a more causative level than solely try to fight the symptoms.

Therapeutic Strategies for Treatment of X-Linked NDI

Because in vitro expression studies reveal that the majority of *AVPR2* mutations in X-linked NDI result in normal protein that is retained within the endoplasmic reticulum (ER), agents that restore plasma routing are under investigation as potential treatments. Promising agents are cell-permeable AVPR2 antagonists and agonists that in vitro rescue the intracellular retention of several AVPR2 mutants [6, 45, 101]. An important problem with the antagonists is that once the mutant AVPR2 is rescued to the basolateral membrane, the antagonist needs to be displaced by high concentrations of AVP/DDAVP to induce cAMP signaling. Therefore, low-affinity antagonists are believed to have the highest clinical value. However, their efficiency in rescuing is lower than that of high-affinity ligands, and the high concentrations required to be administered for sufficient activity by low-affinity antagonists might lead to severe complications in patients. The use of non-peptide agonists has somewhat circumvented this problem since they do not need displacement to activate AVPR2. All high-affinity agonists have been shown to induce receptor maturation as well as translocation to the plasma membrane and to elicit a cAMP response [45].

The feasibility of treatment with these so-called pharmacological chaperones has been tested in vivo. In individuals with NDI who have missense *AVPR2* mutations, Bernier et al. showed that treatment with a non-peptide V_{1a} receptor antagonist had beneficial effects on urine volume and osmolality starting a few hours after administration. However, the long-term effect of this drug could not be tested because the clinical development of this V_{1a} receptor antagonist was interrupted during the course of this study as a result of possible interference with the cytochrome P450 metabolic pathway [6]. Tolvaptan, an AVPR2 antagonist used in hyponatremia and polycystic kidney disease, was recently found in in vitro transfected cells, to rescue the function of the M272R mutation, by allowing both proper glycosylation maturation and membrane sorting and response to DDAVP, but has not been tested yet in NDI patients bearing this mutation [95].

Remarkably, certain non-peptide AVPR2 agonists such as OPC51, VA88, and VA89 were shown to be able to intracellularly stimulate AVPR2 and increase cAMP production and AQP2 translocation to the apical membrane [100]. In contrast to pharmacochaperone-assisted folding and rescue of the receptors, the localization and maturation state of AVPR2 did not change upon activation, indicating that these compounds do not act as molecular chaperones. The mode of action by which receptors trapped intracellularly can still activate their coupled G-protein, and how this stimulates adenylate cyclase is not yet understood. Future in vivo and clinical testing has to confirm whether the pharmacological chaperones or the intracellularly acting non-peptide agonists have the desired positive effects in patients and meet the safety requirements.

In patients with X-linked NDI, bypassing AVPR2 could be an alternative way to treat the disease.

By stimulation of the E-prostanoid receptor EP4, NDI symptoms were greatly reduced in a conditional *avpr2*-deletion mouse model [64]. This was due to raised AQP2 levels, most probably as a consequence of cAMP production caused by EP4 stimulation. A similar effect was seen after stimulation of the EP2 receptor by the agonist butaprost [88]. The EP2 receptor is a more interesting candidate for treatment of NDI than the EP4 receptor since EP2 agonists have already been tested in clinical studies for other diseases and have shown promising results concerning safety issues. However, clinical trials in NDI are necessary to evaluate the effects and safety of EP2 agonists for this disorder.

Another potential therapeutic strategy bypassing AVPR2 could be an activation of the cGMP-signaling pathway. Several groups have shown that nitric oxide donors and atrial natriuretic factor stimulate the insertion of AQP2 in renal epithelial cells in vitro and in vivo via a cGMP-dependent pathway without increasing the expression of *AQP2* [13] and the selective cGMP phosphodiesterase inhibitor sildenafil citrate (Viagra) prevents degradation of cGMP resulting in increased membrane expression in AQP2 in vitro and in vivo [15]. In a small number of NDI patients subjected to clinical trials with sildenafil citrate, no decreases in urine volume or increases in urine osmolality were observed (personal communication in [80]). Alternative AVP-independent strategies are the use of calcitonin, which has a vasopressin-like effect on AQP2 trafficking and urine concentrating ability via cAMP-mediated mechanism [14] and of various statins (simvastatin, fluvastatin) that were reported to increase AQP2 expression and water reabsorption in the kidney via an as yet unknown mechanism [65, 94]. Using a systemic high-throughput chemical screening procedure, Nomura et al. identified AG-490 (an epidermal growth factor receptor (EGFR) inhibitor) as a compound that stimulates AQP2 exocytosis, induces AQP2 membrane accumulation, and stimulates urine concentration in an AVP-independent manner [86]. The EGFR inhibitor erlotinib has been shown to increase AQP2-mediated renal water reabsorption, reduce urine volume, and increase urine osmolality in mice with lithium-induced NDI [17]. The most recent approach to potentially treat X-linked NDI is based on the activation of adenosine monophosphate kinase, an energy-sensing kinase that phosphorylates the Na-K-2CL cotransporter NKCC2 in the thick ascending limb of Henle's loop, by the oral antidiabetic drug metformin. Klein et al. showed that metformin increased osmotic water permeability by increasing AQP2 phosphorylation and accumulation in the apical membrane [56]. Efe et al. demonstrated that metformin improved urine concentrating ability in *avpr2* KO mice [25]. Despite these promising results in in vitro studies and in animal models, none of these compounds have yet been translated into therapy of NDI.

Therapeutic Strategies for Treatment of Autosomal NDI

Similar to AVPR2 mutants, the majority of AQP2 mutants causing autosomal recessive NDI are missense mutations that lead to aberrant folding of AQP2 in the ER. Hence, finding substances that are able to re-establish natural AQP2 folding holds comparable promises for treatment of recessive NDI as it has been shown for the X-linked form. In CHO and MDCK cells, glycerol has proven the applicability of chemical chaperones to AQP2 by restoring ER export in high concentrations [117].

Yang et al. described partial restoration of cellular AQP2 processing upon treatment of conditional AQP2-T126M knock-in mice with an Hsp90 inhibitor, 17-allylamino-demethoxygeldanamycin (17-AAG), eventually resulting in improved urinary concentrating ability [124]. The precise explanation underlying the beneficial effect of this Hsp inhibitor remains to be elucidated. Furthermore, it is not unlikely that Hsp90 inhibition may have severe side effects that outweigh the advantages [115]. Therefore, lengthened studies addressing safety issues of Hsp90 or other chaperone inhibitors have to be conducted in order to elucidate the applicability of these compounds in NDI therapy.

Based on the improvement of AVP-dependent cAMP signaling of collecting duct cells in a hypercalcemia-induced NDI mouse model, Sohara et al. also tested the phosphodiesterase-4 inhibitor rolipram in the knock-in dominant NDI mice [112]. Their data indicated that rolipram is able to increase cAMP levels leading to increased AQP2 phosphorylation and translocation to the apical membrane. Phosphodiesterase-4 is a common protein that also is involved in immunosuppressive and anti-inflammatory pathways, and therefore, its inhibition may have severe side effects. Rolipram has been tested in two male patients with X-linked NDI and did not cause any relief of symptoms [9], but the potential for other PDE inhibitors in the treatment of NDI needs to be examined further. The polyuria described in the patient bearing the autosomal dominant AQP2-E258K mutation [81] is now well controlled by DDAVP, 20 micrograms intranasally bid (D.G. Bichet, personal information).

Therapeutic Strategies for NSIAD

Fluid restriction is the mainstay of treatment for NSIAD [93]. It allows controlling hyponatremia and reducing the risks of neurological complications. This may be challenging, particularly in infants in which excessive fluid restriction may limit caloric intake. Oral urea in these patients may improve urine output by inducing osmotic diuresis [28, 41].
